CLINICAL NOTES ON ASTHMA AND ITS TREATMENT.*

BY BEVERLEY ROBINSON, M.D.,
New York.

Among the diseases the practitioner is called upon frequently to treat, none is of greater interest than asthma. Possibly this interest is due in part to the fact that its immediate causation is at times very obscure.

*Read at the fifteenth annual meeting of the American Climatological Association, at Maplewood, N. H., Aug. 31, 1896.

No doubt, however, it is accentuated much by the fact that when we are sure as to the cause of the asthmatic attack, or condition, we can in many instances be of great service to the sufferer. This statement is, of course, more correct where we encounter cases which are relatively of late date, and where, if the etiology be determined, we can be confident as to our power to relieve or cure.

The cases of so-called nervous asthma, or asthma merely functional and without fixed causation, have been in my experience relatively very infrequent. I do not doubt that they do occur, because many reliable authorities speak of them in no uncertain terms. And yet I do believe, when we are better
informed, such examples of purely functional
asthma will dwindle immensely, and perhaps,
indeed, no longer be described. I do not
wish to be misunderstood. In the majority
of, not to say all, cases of asthma, there is
probably a certain sensitiveness of the central
or peripheral nervous system which accounts
in a measure for the recurrent attacks of this
affection. What I wish to insist upon, how-
ever, or emphasize most emphatically, is that
despite the existing nervous irritability, the
asthmatic attack would rarely occur were
there not some other discoverable cause
which more advanced researches will reveal
to us.

Conditions of the blood are often ignored
which, if closely inquired into, will throw
light upon an otherwise very indefinite causa-
tion. Malarial toxemia is frequently present
and yet ignored. The reason for this is
because, first, malaria may be present, caus-
ing slight enlargement of spleen and liver,
moderate secondary anemia, engorgement of
the nasal, laryngeal and tracheal mucous
membrane, or other parts of the upper or
lower air-tract, and yet be lost sight of, or
its presence questioned or doubted. Again,
this is true where there is apparently no
physical change of organ; and yet constant
or frequently recurring symptoms of head-
ache, backache, disordered stomach, general
fatigue, inertia, irregular, chilly sensations,
inappetence, constipation, or diarrhea, may
be proof of or point toward it. It is wisdom
for an observing practitioner to be quick to
see and act in accord with its recognition.
If a blood examination be made under one
or other of these circumstances, shall we be
definitely informed as to the malarial nature
of the condition preceding the asthmatic
seizure? Occasionally, yes; more frequently,
not to say usually, no, in such instances. If
there has been a sudden chill, followed by
rise of temperature and sweating, and if at
the time of the chill and previous to the
giving of quinine internally a skilful micro-
scopic examination of the blood be made,
the plasmodium malarize should be found
usually, but not invariably. When we are
face to face with the asthmatic attack, how
should we proceed, given a possible or prob-
able malarial causation? If it be only in-
definite, and yet no other cause be found, I
advise Fowler’s solution of arsenic to be
given in increasing doses up to its physio-
logical effect. If the bowels are notably
constipated and the liver evidently inactive,
I advise Warburg’s extract in five-grain
doses three or four times daily. If anemia
be present I advise quinine, iron, and arsenic
in a suitably formulated pill, the following
being a favorite with me: 1 grain of reduced
iron, 2 grains of sulphate, or preferably the
muriate, of quinine, and \( \frac{1}{30} \) to \( \frac{1}{60} \) grain of
arsenious acid, three times daily after meals.
Of course, if the asthmatic attack be severe,
we should also employ our antispasmodic
remedies, such as belladonna, chloral, nitro-
glycerin, etc., judiciously. We should also
permit patients to smoke and inhale from a
cigarette d’Espic, Datura Tatula (Savory
and Moore), or of simple nitre-paper. As a
last resort, an inhalation of a small quantity
of chloroform or a hypodermic of morphine
and atropine may become our only satisfac-
tory help in time of greatest need.

As to gout and rheumatism as causative
factors of asthma, what should be said? I
am in accord with those who find in these
constitutional conditions an underlying in-
fluence of great power in causing nervous
irritability and characteristic appearances
of the throat. Wherever we have the clear his-
tory of a previous attack of acute rheuma-
tism or gout, and where, in addition, we have
cardiac, joint, or renal signs and symptoms
which plainly indicate one or other diathesis,
we rightly infer many times that the asth-
matic attack is of similar origin. Of course,
accidental circumstances, such as over-
fatigue, errors of diet, exposure to cold or
wet, great anxieties or cares, may hasten, or
indeed occasion, an outbreak of asthma,
when without these incidental occurrences
the dyspeptic attack would not have shown
itself.

To indicate how important it is at times to
recognize the inherent gouty poison dormant
in the system, so as to effect speedy amelio-
ration or cure of a patient’s symptoms, I
would refer for a moment to a dear friend
and patient now deceased several years. The
case was that of a lawyer, eminent in his pro-
fession, about fifty years of age, who had on
several occasions gouty manifestations of the
joints, marked torpidity of the liver, and a
considerable deposit of lithates in the urine.
For these symptoms he had been to Carlsbad
for treatment, and, thanks to this cure and
marked abstemiousness in his daily habits, he
was able during quite a while to be in a fairly
comfortable bodily condition. On one occa-
sion, after a prolonged period of rest from
annoying intimations of disease, he was at-
tacked every afternoon at a particular spot,
during his walk up town, with marked dys-
pnea. To explain it, if possible, the urine was carefully examined, the heart and lungs interrogated, the diet and habits rigidly catechized, without any positive finding resulting. Despite the trial of various compounds given, so as to meet rationally any hidden or mysterious conditions which Nature was holding concealed, my patient's difficulty of breathing was in no sense relieved. Finally, I concluded that renal inadequacy, due to gout, was the efficient cause, and that substances ordinarily eliminated through the kidneys, but now retained in the system, were the explanation of his suffering. Proceeding upon this theory, I ordered colchicine granules, one milligramme in each granule, three or four times daily, and very soon my patient was completely restored to health for a time. During a few days following the use of colchicine the urine, which previously had seemed normal, was loaded with lithates, thus showing the action and beneficial effect of the alkaloid. Aside from purely diaphoretic conditions, it is highly probable that anemia, accompanied with constipation, dysmenorrhoea, and pronounced general neurasthenia, is more than sufficient to initiate in certain susceptible women attacks of asthma which can only be effectually treated where these morbid states are judiciously dealt with.

As to reflex causes of asthma. In the nose and throat we find morbid conditions, with which we are all at the present time more or less familiar, that occasion it. When they exist it is clearly indicated, as a rule, to do what is essential to relieve them. Thus, if more or less complete occlusion of the nasal passages exists, owing to hypertrophy of the turbinated bodies, a deviated septum, soft gelatinous polyps, or in children an adenoid growth, is present in the nasopharynx, or much enlarged faucial tonsils prevent normal breathing, we cannot feel satisfied with our care of the patient unless operative interference be undertaken to modify or remove these evidences of disease. While this is true it should be admitted to-day that several prominent throat specialists have exaggerated, or unduly magnified, the diseased conditions of throat and nose as causative in producing asthmatic attacks. I have in mind a physician of prominence in another city who was greatly annoyed with occlusion of the nasal passages from gelatinous polyps. His periodical attacks of asthma had been attributed to their presence. They were skilfully removed by a rhinologist, and yet the attacks soon returned with nearly their old-time severity. I had under my care not many years ago a young man, now a promising political leader, whose nose was greatly obstructed by pronounced deviation of the septum. The drill and trephine were used, and fair nasal breathing thus obtained. Despite this treatment, with satisfactory result from the specialist's standpoint, morphine injections, hypodermically, had to be resorted to on several occasions subsequently in order to afford notable relief to the breathing.

In chronic gastric catarrh, brought on by errors of diet or alcoholic habits, frequent lavage of the stomach and a regulated regimen have afforded great relief in more than one instance to the frequency and intensity of asthmatic seizures. In some instances in which the total acidity of the stomachal contents, taken after a test meal, would seem to indicate, when allied with severe, repeated attacks of gastricgia, a possible beginning of ulcer of the stomach, I have little doubt that a prolonged use of Vichy or Vals water, with an occasional mercurial purgative, not only afforded relief to the stomachal condition, but also lessened the seriousness of the asthma.

We now come to a consideration of what, after all, are the large number of asthmatics we are likely to see. They are the bronchitic cases—cases in which there is also more or less development of emphysema. Taking cold, as it is said, apart from every other consideration, is what seems to the patient the essential cause of his asthma. He will get along peacefully for weeks without any evident pulmonary distress, and then, owing to slight atmospheric changes, wet feet, sitting in a draught, going from an overheated room to the outside atmosphere, very soon he will notice more or less oppressed breathing and all the usual asthmatic phenomena. In very many of these cases, although they may claim that between the periodic attacks they feel perfectly well, yet when they are questioned closely we shall find almost invariably that upon slight exertion they suffer from short breath and cardiac palpitations. If we examine the chest carefully the percussion note, as well as auscultation, shows here and there patches of pronounced vesicular emphysema. The latter may have developed slowly and insidiously; nevertheless, when we watch our patients closely, we shall find that the emphysema extends and involves more lung tissue with the recurrence of each asthmatic attack. The development of the emphysema in its initial stage is not, however,
always obscure or uncertain. Very often, and particularly in children, whooping-cough, croup, enlarged tonsils, acute bronchial catarrh, may have previously existed and are quite sufficient to occasion a slight organic condition of emphysema. Where the emphysema is present, recurrent attacks of acute bronchitis are apt to follow for a very slight cause. The mere fact, for example, of the inhalation of an impure atmosphere for a short time will frequently cause the development of bronchitis. If we listen to the chest we shall find sibilant and sonorous ronchus in abundance, varied at times with moist sounds, even though the secretion is often in small quantity (frothy or viscid), which leaves us in some degree of uncertainty as to the precise condition of the lung tissue.

If the lung, instead of being of good resonance (not to say hyperresonant), becomes, in special areas at least, dull and non-elastic, does not expand as it should, and we also have muffled or bronchial voice and whisper, we are often undetermined in our judgment as to how much pulmonary tissue is involved.

We are also in doubt as to the pulmonary condition in regard to inflammation. Have we to do with bronchopneumonia affecting one or more lobules? Have we a local atelectatic condition due to the plugging with hard, inspissated mucus of a large or small bronchial division? Is it only increased pulmonary congestion accompanying bronchial inflammation? Or, and especially when the râles are superficial and moist, are the pleural surfaces somewhat inflamed, and do their contact and rubbing together give rise in part to the stethoscopic signs we surely find? These and other questions are clinically most difficult to decide and accept for the ipse dixit which at best conceals ignorance. I believe that most men of large clinical experience will reecho my expressed thought. Of course, the presence or absence of fever, the number of leucocytes found in a careful blood-count, the local pain aroused during respiration and cough, will not infrequently help us very much to reach a rational and tolerably satisfactory judgment. Where the bronchitis is clearly defined and the secretion slight, our main effort should be to stimulate the latter by appropriate means, and here I find small repeated doses of ipecac, tartar emetic, grindelia robusta, chloride of ammonium, and iodide very useful. Where the bronchitis is also evident and yet there is much bronchial secretion, belladonna or atropine must be combined in small or moderate doses with the drugs previously named, or be given with a little camphor and quinine in capsule or tablet form, or else, what is often preferable, simply alone, until their physiological effect becomes manifest. Where the emphysema and bronchitis are clearly defined, and where the asthma is also pronounced and threatening, we cannot wait always for the relatively slow and continuous effects of the drugs referred to, and here again we must have recourse for temporary results to inhalation of the fumes of the different antispasmodic cigarettes, of the leaves of stramonium or tobacco, the repeated use of oxygen gas, the timely administration of Hoffman’s anodyne, alcohol, hot coffee, capsules of ether or chloroform, etc., always remembering that in very many cases nothing will give relief even for a while, unless it be chloroform by inhalation or morphine hypodermically.

Where, in connection with the previous conditions, we have evident cardiac distention, as shown by increased area of dulness, epigastric beating, distended jugulars, rapid, depressible, weak, sometimes irregular, pulse, cyanotic lips, face, and finger-tips, we must recur to the use of nitroglycerin or the nitrates in frequently repeated doses; or to a soluble salt of caffeine (salicylate), either by the mouth or hypodermically. Occasionally blood-letting by bleeding from the arm or the use of leeches, or wet-cups to the chest or epigastrium, will afford relief more or less lasting, according to circumstances. Usually, I regret to say, the relief is only temporary, and the weakened, distended right heart is soon again powerless to struggle against the ever-present conditions of lung involvement and vascular and nervous paralysis. It is specially under these conditions that we must be particularly careful in our use of a remedy like nitrite of amyl when used by inhalation, which instead of affording marked relief by relaxation of the arteries only seems to occasion further and more intense pulmonary congestion, and thus adds an additional obstacle in front of a right heart already overtaxed. Within a few weeks of writing this I have had occasion to notice these dangerous effects. In the case of an old asthmatic patient who was suffering, and from whom I was desirous of withholding a morphine injection in the fear that it be repeated too frequently and thus give rise to the morphine habit, the rapid inhalation of only three minims of nitrite of amyl increased the dyspnea suddenly to a most alarming degree. The veins of the neck became largely dis-
tended, the face intensely cyanosed, the eyes suffused, glassy, and so prominent as to appear to start from their cavities. Frequent and labored breathing developed immediately, followed by repeated efforts of expectoration, during which sputum partly frothy, partly thick, and mucopurulent, was expelled with great difficulty. All these and other serious symptoms gave rise to a graphic and distressing picture not soon to be forgotten.

In a short while, however, thanks to the timely help afforded by a hypodermic of tincture of strophanthus, there was a visible temporary amelioration. Despite our best efforts, however, the patient failed rapidly, and died a few days later. At the autopsy the most marked pathological feature of the case was the advanced degree of pulmonary emphysema. In one spot on the anterior border of the right lung evidently one or more of the marginal vesicles had been ruptured, and we noticed a very large sac filled with air and surrounded by the visceral pleura. The sac itself was equal in size to a turkey’s egg.

One of the difficult matters to decide in the treatment of asthmatic attacks is when and how frequently we should give morphone injections hypodermically. In the majority of cases that have come under my care I am confident that no remedy will give such immediate and considerable relief to the acute suffering. On the other hand, we have the just dread of beginning a habit so pernicious and so difficult to cure, if once established, that I am compelled to counsel great care in its use. This counsel is eminently wise for attacks, even though severe, that are often repeated.

Again, it should be known that morphone injections will not invariably afford relief. There are times when morphone in any ordinary dose will aggravate rather than subdue the attack, and even add gastralgia to the intense dyspnea from which the patient is already suffering so much. When, moreover, the patient’s urine contains an appreciable amount of albumen and affords other evidences of nephritis, it is often very hazardous to recur to the use of morphone. This is particularly true where the pupils are notably contracted. I have good reason to believe that by administering morphone under like circumstances we may precipitate a rapidly fatal uremic attack.

The question of change of locality is frequently one which arises and which is so difficult to solve. In general, we would have our patients seek atmospheric conditions quite dissimilar to those in which the attack originates and continues despite our watchful care. If the patient be resident of a city or large town, first of all we should have him change his neighborhood for awhile, and often even this slight change is useful. If this proves unavailing, and he be living near the coast, we would have him go to some healthy inland place of moderate elevation, free from dust and cutting winds, if possible. If the town be inland where the person first becomes a sufferer, we should strongly insist upon a prolonged stay by the sea. And yet I regret to add that all our efforts in this direction are often unavailing and the patient continues to suffer about in the same way, no matter how often we change the locality in which he lives. There may be and often is temporary relief. Quite frequently we learn with great satisfaction that the patient has obtained just what he most desired, viz., relative great quiescence from suffering, or, indeed, the diminished frequency of the attacks. Unfortunately, we cannot count upon this well-being as durable, and sooner or later the asthma is prone to return with its former intensity. Personally, I am inclined to believe, after considerable experience and reflection, that the climatic conditions which shall prove best for any particular case of subacute or chronic bronchitis are also those best suited to the bronchitis when complicated with asthma.

**DISCUSSION.**

Dr. F. I. Knight: I think Dr. Robinson has done a good service now and heretofore in calling attention to the constitutional element in cases of asthma. The gouty or the malarial condition which is often the excitant of the attack is undoubtedly often neglected. It seems to me that asthma is a very complex thing. Asthma is due, first, to an underlying neurosis; secondly, to some lesion in the bronchial tract, I think almost invariably, if not always; and thirdly, to some excitant. In treating the paroxysm, if we can relieve or modify any one of those factors we can stop the paroxysm. I had a patient who could always relieve an attack of asthma by gambling for high stakes. It is possible, in certain cases, to change or alter the organic lesion; but we can remove the excitant, or remove the patient from the excitant. Englishmen who are subject to asthma will relieve it at once by going from the country up to the city. I know a patient who
always has asthma in one hotel in Boston and never has it in another, and the hotels are within a block of each other; and no one has been able to tell the cause. So we have these various factors on which we may work in the interval. The gouty or malarial constitutional condition which I consider the excitant may be so modified that the patient's attacks may be relieved; so it is with those cases where an organic lesion in the upper part of the respiratory tract acts by reflex on the air-tubes below. Often when polypi are removed there is only temporary relief, and then some other irritant comes in by reflex or otherwise. I might mention here the theory of Berkart, that the lesion in ninety per cent of cases is in the lungs, and comes from measles or whooping-cough or other inflammatory affections of childhood. Dr. Hyde Salter put the proportion at eighty per cent. I think this may be an exaggerated statement, but since reading it I have traced a large number of cases back to inflammatory conditions in childhood. In regard to the bronchial cases and their relief, I should, perhaps, urge more strongly than Dr. Robinson the value of the iodide of potassium. No one remedy has served me so well as this. In the epiphysematous cases there is one thing which above all should be insisted upon, and that is rest. The patient who has been miserable with repeated attacks of asthma at night for weeks and months may be, perhaps, relieved for considerable time by restricting his movements and administering strychnine freely. It is an interesting subject, but certainly a very perplexing one, and worthy of a great deal more study than is usually given it; and if men will take the pains to investigate individual cases and not consider them simply cases of asthma and treat the name, but will try to get at the conditions which underlie them, they will have much better results in their attempts at treatment.

Dr. V. Y. Bowditch: It is an interesting fact to me that not many weeks ago Dr. A. C. Klebs, of Chicago, lately of Citronelle, Ala., told me of some striking results from the use of diphtheria antitoxin injections in cases of asthma, at the suggestion of (I think) Revil-lod, of Geneva. Although very skeptical as to its efficacy, he had tried it in the case of a young girl, about ten years old, who had been subject all her life to attacks of asthma. In her case he had used it once or twice with apparently very marked benefit. The patient is really too young to have the mere moral effect of trying a new remedy in such cases taken much into consideration. In another case very marked improvement was noticed in a lady who for years had been a great sufferer, and who had tried almost every known remedy. The good effect of each injection, moreover, lasted many weeks, and at last accounts she was better than for many years before. I give these suggestions for what they are worth without further experience. They come from a careful and cautious observer, not easily convinced of the efficacy of new remedies, but who was at the time certainly impressed.

Dr. Frank S. Johnson: I wish to add my testimony to what Dr. Robinson has said about the condition of constitutional infection, and the necessity of determining primary cause. But in almost every case of asthma, whatever the primary cause may be, we have to deal with bronchitis and spasm, and in order to obtain prompt satisfactory results, no matter whether the primary poison is eliminated or not, we must direct the treatment temporarily to the immediate disturbance. I concur most fully with what Dr. Knight has said, that the most important remedy is iodide of potash. It should be given in moderate doses, continued for weeks or months, if need be. The relief of the paroxysms is the important thing in the patient's extremity. In mild attacks this may be accomplished by the administration of belladonna and chloroform internally. Chloroform given internally acts more slowly than by inhalation, but the action is more prolonged, and it is safer. In severe paroxysms the nitrites are often very useful. I prefer nitroglycerin. Its action is very prompt, almost as prompt as nitrite of amyl. The vasomotor effect of one one-hundredth of a grain can often be felt within two minutes. The dose may be repeated every ten to sixty minutes as required. Nitrite of amyl is much more dangerous in the hands of the patient than nitroglycerin. Morphine is safer and more useful than the nitrites in asthma with greatly embarrassed right ventricle.

Dr. J. B. Walkler: I would like to refer to one climatic factor that is within every one's reach everywhere. This is sunlight. A patient living on one side of a street may be exempt from asthma, while on the other he may be affected. This may be due to the fact that on one side he lives in a shady room, and on the other side in a sunny one. This is a factor of no small moment in not only the asthmatic, but in all subacute and chronic bronchial disorders.
Dr. R. G. Curtin: Dr. Walker's remarks about a person being able to live on one side of the street and not on the other recalls to me the history of a case. Some of you probably know that Market Street in the past was supposed to be the dividing line between the older and the newer society of Philadelphia. A man who lived on Walnut Street at that time found that if he walked across Market Street toward the north he would instantly have an attack of asthma, which was relieved by returning to the south side. Dr. Knight's patient reminds me of a confirmed asthmatic who, whenever he had a severe attack of asthma, was always relieved by sitting on a chair in a cool damp cellar when the day was hot and dry.

Dr. Jacobi: I think, Mr. President, the ground has been gone over pretty thoroughly, and nothing has been left untouched. Reflex neurosis, particularly nasal, I have myself charged with being the occasional cause of asthma, but I know that the large majority of cases of asthma I have seen were connected with bronchitis. There is rarely a case that will not exhibit the symptoms of diminished respiration and some dulness over small parts, very frequently over large parts, generally posteriorly and over the lower lobe. It is mainly these cases that are benefited by iodide of potassium. They are not so much affections of the mucous membranes as of the connective tissue of the bronchial tubes and their surroundings, with thickening of the walls. The term "peribronchitis" has been dropped by a great many, but I think it is a good word to show exactly what it is meant to signify. As the attacks mostly come on in the night, I do not hesitate to give a dose of morphine, with or without chloral hydrate, every night for a long time, and not infrequently it will be the first step in the treatment of a cure. I give good doses, always the same. I never had to increase it, and never developed a case of morphinism in an asthmatic person so treated. Then, it is necessary that the window should be open enough to admit air. The attacks come on when there is carbonic acid and other poisonous gases in the air, when the medulla oblongata is oversupplied with carbonic acid and undersupplied with oxygen. As far as emphysema is concerned, it may be sometimes incurable, but it can be benefited a great deal. One other thing: let your patients be practised in forcible expiration, which may be helped along by compression of the diaphragmatic region, according to the plan of Gerhardt and others. The patient may use a towel for that purpose, which he works himself. An additional help for the purpose of improving expiration is snuff. I make them sneeze very hard four, five, ten times every day—a very satisfactory method, and not very expensive.

Dr. J. H. Musser: In the management of this affection reference has been made to, and I concur in the necessity of, hygienic and largely to dietetic measures for its relief, not excepting climatic influences. With regard to remedies, asthma is the disease which exemplifies the law that the more incurable the disease, the more remedies there are for the affection. It certainly is a disease that requires the study of each individual case. I am satisfied in a number of cases, as Dr. Jacobi remarked, that sedatives are very beneficial. I am sure I have seen, barring the fact that the disease may probably have disappeared independently of my management, one instance where the use of morphine every night, hypodermically given, cured the patient. The object was to anticipate and prevent the occurrence of the paroxysm. The patient was in the family of a physician, and the physician was able to watch the effects, beginning at first with doses sufficient to control the spasm, and each night lessening the dose, until finally the patient was able to do without the mor-
well are strontian salts and nux vomica. Nux vomica has been very satisfactory, continuing it over a long time. Such dose is given as produces physiological effects, then reducing the dose, bearing in mind always that the patients become accustomed to the remedy. From time to time you may increase the dose in order to get its effects. In this manner I have had patients take as much as one hundred drops of tincture of nux vomica three times daily. In another instance with the nux vomica given in this manner and the morphine at night, watching the effects and gradually diminishing the dose of morphine, I have one patient absolutely cured. There may be other drugs that occur from time to time which may be of use, but these are the remedies that occur to me. We must not forget in the treatment of asthmatics the value of inhalation, and especially of treatment directed to the local condition. In examining the sputum of many of these asthmatic patients we find the infection of streptomycoci, indicating that there is a localized infection. These cases I am sure are the most difficult to manage, and for them we must resort to climatic influence.

Dr. Blackader: We all agree, I am sure, with Dr. Musser in emphasizing the importance of first removing, as far as possible, any reflex source of irritation, and then carrying out a vigorous constitutional treatment of the disease. Personally I agree with him as to the value of morphine in relaxing spasm, if employed with caution over short periods of time; but I differ from him when he minimizes the danger in these cases of the morphine habit. There is, however, another drug of which I stand in still greater dread. That drug is cocaine. Two patients of mine who, to obtain relief from a troublesome bronchial asthma, were sent to climatic resorts in the South, returned slaves to the local employment of cocaine. When nasal troubles exist, the relief that cocaine affords is prompt, but only temporary. In the end it unquestionably increases the local damage; more important still, it ruins the patient morally. As a society we should raise our voice in condemnation of its use.

Dr. W. D. Robinson: Exhibition of iodide of potassium causes gastric distress and nausea. When given in junket it can be safely administered without trouble, and the doses largely increased.

Dr. Musser: I want to indorse what Dr. Blackader said in regard to cocaine. It is infinitely more dangerous than morphine.

Dr. Coleman: I want to speak in corroboration of what Dr. Blackader said concerning the use of cocaine. I have a patient now under my care who has become addicted to the cocaine habit by using it as a spray, and he uses as much as an ounce of the crystals in two or three days. I do not know of any such amount ever having been taken, but he has reached the point where he can scarcely go for fifteen minutes without using the spray.

Dr. E. O. Otis: Reference has been made to the beneficial effects of removal from one room to another, and from one side of the street to the other. As illustrative of this, a case occurred to me a few days ago where the asthmatic paroxysms were most severe and distressing, and in relieving which all the ordinary and extraordinary methods of treatment failed, including subcutaneous injections of morphine, and momentary relief was only obtained by the inhalation of ether. The removal from one room to another, and the substitution of pillows made of other material for feather ones, appeared to be the determining factors in relieving the attack.

Dr. Robinson: I have two things to say; one is for the people: I trust that if any ladies and gentlemen who are now in this fair region have been willing to listen to what has been said, they are also willing to recognize that it is wisdom to take no panacea for the relief of asthma, but to put themselves in charge of a far-seeing and intelligent physician.

One point not referred to in my paper is a question in regard to the use of morphine. I have been on the lookout for it, but have not yet struck it. A point I made was in reference to the use of morphine injections in uremic conditions, and as to when we could use morphine injections to break up uremic convulsions, and when not. We all know that the late Professor Loomis certainly acted in a very able and satisfactory manner when he showed us in certain acute conditions there was nothing better to break them up than injections of morphine; but we also know that in certain cases of chronic nephritis it is a very dangerous remedy. In looking over Dr. Loomis' cases I notice that in every instance, without exception almost, where it is mentioned, the pupil is indicated as being dilated. Wherever a patient is shown to have kidney trouble I always look at the pupil before I give my hypodermic of morphine. If contracted I will not give it. In chronic asthma recollect that we have to do with
people of a certain age and a certain amount of interstitial nephritis. Many have a certain amount of albumen in the water. I think that the question of whether they have interstitial nephritis will depend upon the specific gravity of the urine. We are not always able or ready to make a careful urinalysis and estimate quantitatively what there is to be found, and I simply direct attention there. Knowing as we do that the interstitial nephritis probably exists, and with an interstitial nephritis that there is a considerable risk at times in giving morphine injections, let us be a little bit careful.

MEDICAL SKEPTICISM.*

BY WARREN E. HILL, M.D.,
Professor of Materia Medica and Therapeutics, Milwaukee Medical College.

Medical skepticism is a malady that has afflicted the medical profession for a great number of years. In ancient times, and even to within the recollection of the "oldest inhabitant," medical credulity held sway. As empiricism gave way to rationalism a pronounced tendency manifested itself in the profession toward medical skepticism. All that was exact in medical science was attributed to surgery, and it, being a simpler study than internal medicine, readily adapted itself to the conditions brought about by recent investigations along the lines of bacteriology and pathology. Surgeons have always been more or less skeptical regarding the action and effects of internal medication, and it is a deplorable fact that some of the most eminent writers of our day on practice of medicine and therapeutics have distrusted the remedies which they were obliged to use. This condition has spread to such an extent among the profession at large that the interest manifested by them in therapeutics is so slight that the committee of arrangements of our State Medical Society had provided only one paper for this branch of medical science on its annual programme, while the attention of the profession is directed towards surgery, where to see is to believe.

These are lamentable facts when one takes into consideration that a large proportion of these cases coming under the observation of the practitioner are curable by internal medication, and the entire work of anatomy, physiology, pathology, etc., is but the foundation for which therapeutics should be the superstructure. Paraphrasing the Bible, Barthlow has said that the three medical graces are diagnosis, prognosis, and therapeutics, but that the greatest of these is therapeutics.

It is therefore the purpose of this paper to discover, if possible, a cause for this skepticism and to suggest a remedy. Owing to the fact that there is a tendency in a large percentage of cases toward recovery without medical interference, it is impossible for us to determine exactly the importance of drugs in the cure of disease. Idiosyncrasies and the "personal equation" are factors which circumscribe our efforts toward exactness in internal medication, but that which shakes the faith of the greatest number in drugs and sends hundreds of practitioners, both young and old, over to the side of skepticism is the unreliability of the preparations of drugs as found in the open market. There is annually placed upon our market thousands of pounds of ergot which has little or no therapeutic value, and yet we do not know enough of the chemistry of ergot to make a chemical assay for our own protection. The activity of the various samples of strophanthus varies to such an extent that Dr. Houghton, in determining the minimum fatal dose per gramme of weight, found that in fourteen samples there was a variation of .00010 to .00033 cubic centimeters, which shows that had tinctures been made of these various samples one would have been more than three times as strong as another. Of all the important drugs of materia medica, perhaps there is none more variable in its activity than cannabis indica, yet it is impossible to make a chemical assay because, while the active principle of hemp is a resin, there are other resins which are inert and inseparable from the active one.

These are a few of the difficulties in the way of procuring physiologically active drugs. If the crude drug is variable in activity, then the preparations must also be, and if we are not able to prescribe with precision we are prone to become skeptical. There is even such a variation in the activity of glucosides that one sample of strophanthin was found to possess ninety times the activity of another, yet both samples were purchased as pure strophanthin. In the light of this fact is it strange that a doctor, having used a drug with success upon a patient and subsequently, under the same conditions, found it to be
absolutely worthless, should renounce drugs as feeble and uncertain remedies in the light of modern research?

The Remedy.—The remedy for this state of affairs lies in the revision of pharmaceutical methods. It is possible to have physiologically active drugs. Those whose activity is represented by chemical compounds susceptible to isolation, such as alkaloids, should be chemically assayed, and the physician using them should either procure such galenical preparations or use the alkaloid itself. Those drugs whose activity resides in the unstable compounds, such as glucosides, which are so easily decomposed as to make their isolation and chemical assay uncertain, should be tested physiologically before being placed on the market. Ergot may readily be tested by its effect upon the circulation of the combs and wattles of cocks. The activity of cannabis indica may be determined by the incoordination which it produces upon lower animals, such as dogs, while those drugs which influence blood-pressure and respiration may be tested upon lower animals by the kymograph, and other apparatus devised for that purpose.

The practice of using animals to test the physiological action of drugs is not a new one. Indeed, nearly all of the drugs which have been brought out in recent years have been tried physiologically upon the lower animals in order to determine their therapeutic value; but up to the present time there has been but little done in this direction for the purpose of determining the activity, physiologically, of drugs before putting them on the market. Most of this work has been qualitative, but since the advent of serum-therapy a quantitative assay has been made possible. All diphtheria antitoxin has been subjected to this quantitative test, and while we do not know the active ingredients of the serum, we measure its dosage in a unit of physiological activity. The same process is possible in determining the exact physiological strength of galenical products made from drugs which are not amenable to chemical assay.

In a paper read before the American Medical Association, Dr. Houghton, director of the pharmacological laboratory of Parke, Davis & Co., describes his method of standardizing tincture of strophanthus by physiological tests, which is briefly outlined as follows:

Having determined that the minimum fatal dose of tincture strophanthus will average about .0,00015 Cc. per gramme weight of frogs, when a new lot of strophanthus seed is to be tested a number of frogs of approximate weight are divided into batches of five. The first batch is injected with a minimum fatal dose of a standardized tincture, which should kill about three out of five. A tincture is now made by the customary formula of this new lot of seed, and another batch of five frogs is injected with this product. If this does not have the same effect as that of the standardized product, a second or third batch is injected until the minimum fatal dose is obtained. This is compared with the standard fatal dose and an estimate made as to the variation. A new tincture is now made, taking such variation into consideration, and a sufficient amount of the crude drug used to make the product equal to the standardized product. This is again injected into a batch of five frogs, and if the result is satisfactory, the formula used for making this tincture is used for the entire lot of the drug from which the sample has been taken. With a tincture of this kind it is possible for the physician to prescribe with a great degree of precision, and my own experience with drugs physiologically standardized has convinced me that medicine is a much more exact science than it is credited with being. This method of standardization may be employed in the manufacture of preparations of many drugs, and I believe it would be wise, in the revision of the Pharmacopoeia, to have an important place given to physiological standardization of important drugs which cannot be chemically assayed.

THE THERAPY OF IRON.

By A. L. Benedict, M.D.,
Professor of Physiology and Digestive Diseases, Dental Department, University of Buffalo.

In regard to therapy with iron, there are many factors to consider, pro and contra. First of all, we must answer the arguments of those therapeutic nihilists who insist that iron, at least in inorganic combination, is not absorbed by the body and that the administration of the ordinary official salts can have no possible effect beyond preventing the elimination of iron by the body. On the face of the matter, it is apparent that those who hold this view claim either too much or too little. If we grant that iron introduced into the alimentary canal forms no part of the body, how can its mere presence in the stom-
ach and intestine prevent the elimination of iron from the tissues? We certainly know of no function of iron, either elemental or in compound, that is performed within the digestive tube. Neither is it rational to suppose that iron is eliminated from the body for the mere sake of having it appear in some of the excretions. Perhaps it is entirely a waste of time to refute this belief, which is really nothing but a half-understanding of Bunge's theory that inorganic iron in the intestine united with hydrogen sulphide and thus saved the iron in organic combination for more useful purposes. A number of experimenters have opposed their results to Bunge's, among them Honigmann, who noted the intestinal contents as they passed a fistula in the lower part of the ileum of a patient. There was no evidence of hydrogen sulphide formation—though no elaborate chemic test was made—yet only a fifth of the iron administered by mouth appeared in the feces at this point, allowing for the average amount found in food under ordinary diet. With evidence of this nature there seems to be no tenable position, except the rather optimistic one that prevails among most physicians and the hypothesis that iron absorbed from inorganic compounds administered by the mouth is speedily eliminated again without really ever having been assimilated. It is hardly necessary to point out that the assimilation of iron means the formation of hemoglobin, since in no other form does iron appear to have any function in the body or to exist except as a matter of accident.

Dr. A. Hofmann, of Zurich, has reported in the Archiv für Path. Anat. und Physiologie, und für Klinische Medicin, March 9, 1898, a series of experiments in regard to the absorbability of iron both in human beings and in animals. In his review of the literature of the subject it appears that Quincke in 1868 experimentally demonstrated that animals fed with inorganic iron compounds absorbed them, at least from the duodenum, and under some circumstances from the stomach and jejunum. Before this, the same view had been upheld, but not conclusively demonstrated. It may be said that all experiments of this nature depend upon the precipitation of iron in the tissues and the demonstration of a staining, either macroscopically or microscopically. With the exception of Bunge, in 1885, the various observers are in close agreement that the principal depots for iron in the body are the liver and spleen, that its elimination occurs mainly from the large intestine, slightly from the kidneys, scarcely at all from the biliary passages or the small intestine. Why Bunge alone has been thought worthy of credence is a mystery.

In six human cases in which iron had not been administered medicinally, Hofmann made careful examinations of the alimentary canal, liver, spleen, and kidneys, using ammonium sulphide as a better reagent than potassium ferrocyanide, etc., whether for naked-eye demonstration or for microchemic preparations. He found that an abundance of iron could always be found in the spleen, as would be expected from the blood-elaborating function of this organ, and especially the breaking up of senile red cells in its pulp. It is scarcely necessary to remind the readers of this paper that hemoglobin will not react like inorganic compounds of iron and that incineration is necessary to reduce it artificially to the inorganic state. The liver always contained iron, but in varying quantity. Only occasionally, and then scantily, was iron found in the intestinal walls or the kidneys. In four other cases, iron, corresponding to about six centigrammes of the element daily, had been administered for some time and up to within a day or so of death. In this series iron was demonstrated in the duodenum in considerable quantities, in the large intestine in considerably less amount; otherwise the results were the same as in the preceding cases. Microscopically, about two-thirds of the villi of the duodenum contained iron, as shown under low powers, or macroscopically by a diffuse greenish tint; under high powers iron was shown to be present by the presence of small kernels in the epithelium and larger masses within the villi, the latter being borne mostly by round cells—lymphocytes—toward the submucosa. At first sight this would seem at variance with the classical analyses of lymph of the thoracic duct, as given by Gamgee and others. But it is evident that the analysts chose cases not under iron medication, and therefore subject to only minute traces of iron. It is supposable also that the iron may be diverted from lymph-channels into blood-vessels before reaching the thoracic duct.

For the individual in health all the various chemic needs of the organism depend for their satisfaction upon the natural appetite for organic foods, with only two exceptions (not counting oxygen), the appetite for water and that for sodium chloride, the latter being
apparent in many of the lower animals, as is evidenced by the salt licks of western streams and the eagerness with which domestic animals on a farm crowd about a salt dish. With these exceptions, the fulfilment of the chemic needs of the body is rather a matter of accident. To be sure, any marked deficit of fat, carbohydrate or proteid usually soon produces a corresponding craving, but unless we consider the appetite for meat as indicating a need of hemoglobin—which is contained in muscle as well as in blood—the supply of the other mineral ingredients of the body is not regulated by appetite, and in the natural state the body must select what it needs from a relative excess of all. Anemic human beings do not, as a rule, exhibit an appetite for foods rich in iron, although animals and men who have become anemic from starvation or from deprivation of iron—containing foods, and who are not otherwise abnormal, are said to have a predilection for meat, yolk of eggs, spinach, and other foods rich in iron. The promoters of certain therapeutic preparations of iron have even described an iron hunger for these preparations mixed with milk, etc., manifested by dogs which had been purposely fed on a diet poor in iron.

As a practical point in dietetics the writer has long emphasized the importance of maintaining a fair variety, even in cases of dyspepsia, because of the practical impossibility of calculating and supplying artificially the sixteen elements normal to the body by a restricted diet. Most writers on this subject, and all who are biased by commercial considerations, think they have solved the problem of dietetics if they administer the requisite amounts of fat, carbohydrate, and proteid. Even the pictures used to advertise the merits of artificial foods for infants usually show plainly enough a fat but pale and pudgy baby in marked contrast with the leaner but harder and rosier child that has been nursed and occasionally treated to a bone to suck. One of Hofmann's series of experiments on animals clearly shows the benefits of green foods so long advocated clinically. Taking every precaution to exclude extraneous sources of iron in the construction of the cages and to remove the feces so that these could not be eaten again by the animal, a contrast was made between animals fed on gruel and those fed on green food. The latter showed a marked superiority in iron.

In order to demonstrate beyond question that the coloration of iron in the colon indicated elimination and not reabsorption—the latter theory naturally asserting itself on account of the importance attached to rectal nutrition of late years—Hofmann tried two series of experiments, the first showing that the coloration of the colon persisted after iron administration had ceased for several days, the second that it was maintained during and after iron medication by hypodermic or intravenous injection. During these experiments the duodenum—the organ par excellence of iron absorption when this remedy is given by the mouth—remained nearly free from traces of iron.

It will have been noted that Hofmahn's experiments are contradictory to two time-honored theories regarding the physiology of iron: that it is absorbed from the stomach as a chloride or chloralbuminate, and that iron salts, like other soluble drugs, pass immediately in the portal circulation to the liver. On the other hand, they confirm the theory that, in the spleen, senile red cells are broken down, and that the hemoglobin minus the iron is eliminated as biliary pigment, while most of the iron is reused. It is perfectly possible, however, that iron is absorbed directly from the acid stomach or even from the bowel by blood-vessels. Naturally, this method of absorption would not allow such delay of iron in the wall of the alimentary canal that it could be demonstrated by color reactions after autopsy.

The writer has delayed for some time an article on the therapy of iron, hoping that some such article as Hofmann's might appear to confirm the earlier scientific experiments on the subject and the conviction of many clinicians. It is obviously impossible in the practise of medicine to demonstrate conclusively in any particular case the reality of the benefit of tonic drugs. Such medicines act slowly; they produce no conspicuous phenomena such as may be observed from the administration of even therapeutic doses of alkaloids. Iron, in particular, is essentially a food, and is always to be found both in the body and in the contents of the alimentary canal. Hence the skeptic can be convinced only by methods which are at least relatively quantitative and distinctly local. Intestinal fistule are rare, and those of the duodenum almost unknown. Hence it is difficult to imagine an elucidation at all comparable to Hofmann's being made on the living subject.

As to the choice of preparations of iron, the writer has never been able to observe much
difference except such as might be attributed to some complicating circumstance. In sub-
acid dyspepsia the liquor or tincture of the chloride is particularly beneficial because of the acid present in excess. The importance of having the tincture of sufficient age to contain compound ether has not been apparent to the writer, perhaps because he has been more interested in the stomach than in the kidney. At the same time it is only fair to state that with a moderate experience in chronic Bright's disease the special virtue of this preparation and of the Basham's mixture has never been conspicuous, and the writer cannot refrain from expressing the opinion that if iron is given without reference to a possible effect upon the kidney, and some such diuretic as potassium acetate or pure water or fruit juice is administered to get the precise effect needed so far as elimination is concerned, better results will be obtained than if the attempt is made to kill two birds with one stone.

Neither does it seem wise to administer astringent salts of iron for a local effect on the alimentary canal. Such are certainly contraindicated in gastric ulcer, while for the intestine there are far better and less irritating astringents, and the iron might better be given in as mild form as possible.

The so-called pyrophosphate, the vegetable salts, reduced or powdered iron, Blaud's mass and the newer preparations supposed to represent the virtues of hemoglobin have not given discriminating results in the writer's hands. All are quite unirritating; otherwise the choice depends mainly on whether a liquid or dry preparation is desired. If it is necessary or advisable to give an organic form of iron in anemia, there is little excuse for stopping short of hemoglobin itself. In most large cities it is possible to obtain fresh blood from animals declared to be free from disease by inspection. Not very rarely it is possible to find a patient who will take the trouble to drink fresh blood and who can readily overcome the antipathy to it. But hemoglobin exists also in muscle, though only in a seventh to a twentieth of the proportion in which it is found in blood. However, including the blood that is usually present in meat, a pound of lean beef contains about seven grammes of hemoglobin, corresponding to about three centigrammes of iron. Now if a patient is in such a condition that he cannot assimilate enough iron from the ordinary ration of meat, it is not likely that he will assimilate artificially pre-
pared imitations of hemoglobin. But it is possible that inorganic forms of iron, being enormous in amount as compared with the iron that can be introduced in food and minute as compared with the bulk of foods that contain iron, and being also aseptic and slightly antiseptic, may still be absorbed and assimilated by the organism. Scientific experiments show that this result is perfectly possible. Even in the diseased human system clinical experience shows that it actually takes place, though not in every case in which it is desired.

As to the albuminates and peptonates of iron, it must be apparent that any mineral salt of iron given on a full stomach will form some such compound, while there is no preparation more palatable and more elegant than the albuminate formed by adding a ferric salt to egg-water or milk—omitting, of course, any allusion to the aromatics, sugar, etc., with which commercial products are usually combined.

It has been claimed that the treatment of anemia with iron is superficial and that the truly scientific treatment consists in administering a potassium compound, with or without iron, since in anemia the blood tends to become less alkaline than normal, and especially on account of the deficit of potassium. This claim is true, if the potassium dosage depends on an accurate estimation of the lack of potassium and of alkalinity in the blood. If, on the other hand, as is often the case, it means only that the physician gives Blaud's pill or some similar preparation as a matter of routine, what has been called science is nothing but a fad. Here again the writer would like to emphasize the need of giving green foods and to call attention to Bouchard's experiments in regard to "autointoxication," which show the danger of potassium in excess.

The key-note of successful iron therapy is to recognize that this drug is a food, and that if it is not absorbed and assimilated from an ordinary ration the trouble lies essentially with the body and, according to Hofmann, with the duodenum. This statement might seem inconsistent with others made in this article, and, indeed, it is only our relative ignorance that justifies the administration of iron as a drug at all. But we have plenty of precedent for such administration. Thus, when we cannot make the stomach secrete enough hydrochloric acid we administer the chemical; we even give bile instead of stimulating its formation in the
body. Unfortunately, we sometimes give it when there is already too much of the biliary constituents in the system. Caffeine is only a slight modification of xanthine, which is normally formed during the catabolism of nuclear tissue. If the body cannot assimilate fats we administer the nastiest oil that human ingenuity has devised, and even claim special virtues for it. Thus we are fully justified in administering iron as a medicine, but we must recognize the fact that as soon as we understand and can remedy the fundamental causes of iron deficit we shall sweep all the preparations of iron out of the Pharmacopoeia. Whether we can actually reach this point in practice is by no means certain, but we must regard the anemic patient as having a special form of indigestion or of malassimilation in regard to iron.

There are two significant clinical facts which receive added significance from Hofmann's localization of iron absorption in the duodenum. First, it has long been known that whenever a patient lacked some special food, like fat, or iron, or carbohydrate, he was rather apt to be injured by forcing the administration of that substance. This is particularly the case in diabetes, and while persons who need fat are not usually seriously injured by the attempt to increase its absorption, the fact remains that the more a person needs fat the more obstinately does his system refuse to accept it. Secondly, anemic patients usually present some one of a number of conditions which may be considered as interfering with the function of iron absorption by the duodenum. Hyperchlorhydria sometimes exists, and we may assume as a hypothesis—it is nothing more—that the irritation of superacid chyme flowing over the duodenum inhibits its function. Subacidity would have a similar effect from allowing malfermentation or even putrefaction in the stomach. Ischochymia from any cause would have, ultimately, the same action. Catarrh about the bile-duct or a disturbance of biliary secretion would act locally on the very part of the duodenum which Hofmann has identified with the absorption of iron. Hitherto we have supposed that dyspepsia interfered with absorption of iron because the latter function belonged to the stomach, but this does not apply to anemia with hyperchlorhydria in the absence of hemorrhages. As to the liver, if Hofmann's conclusion is correct, we must have confused cause and effect, and we ought now to modify our conception by assuming, not that the liver is injured by iron carried to it from the stomach and intestine, but that the hepatic, or rather biliary, disturbance prevents the absorption of iron, possibly by what is largely a merely chemic precipitation by biliary acids. Of course, there is nothing in the newer theory to prevent a continuance in the belief that iron may exert an unfavorable local influence on the intestine. But if our premises be correct, we have an indication which the writer intends to carry into practise, of using iron hypodermically, when it is not well borne or is not efficient during administration by the mouth.

From the entire study of the subject it appears that we cannot hope, in the case of the kidney, to secure a local therapeutic effect from the use of iron, any more than we need fear such effect in the case of the liver.

It seems to the writer irrational to administer iron medicinally without carrying on routine blood examinations to determine whether the particular preparation is doing good in the individual case. On the whole, the simplest way to determine this point is by means of the hematokrit. Counting the red cells answers about the same purpose, but it is more tedious, and we are more interested in volume than in number. To be thoroughly logical, we ought to estimate the amount of hemoglobin, but there is, as yet, no clinical method which is reliable. Colorimetry is notoriously inexact and is being abandoned for approximation by specific gravity. But more careful studies of this method show that it contains many fallacies both of technique and of intrinsic nature. Men who object that the hematokrit does not apply to the point in question, but to the volume of cells only, will use an ordinary urinometer for taking specific gravity of a benzol chloroform solution, will neglect to make correction for variation of temperature, will overlook the fact that this mixture evaporates so rapidly and so unequally that it cannot be weighed in an ordinary accurate balance because the weight changes more quickly than the proper weights can be selected, will overlook also recent German studies which show that specific gravity is a function of several variables, including the number of red and of white cells. The writer hopes to obtain practical results from the direct estimation of iron in the blood without subjecting the patient to more than slight bleeding. But as yet this method is not on a clinical basis.
It has often been proposed to use substitutes for iron which are not normal constituents of the body. The chief drugs used in this way are manganese and arsenic. Most clinicians will agree with the writer that the former is practically worthless, and it is gratifying to note that microchemic investigation of the intestine fails to demonstrate that this drug has any influence on the absorption of iron, while there has never been a demonstration that it took the place of iron in the system. With arsenic, clinical results are very different. Indeed, one might perpetrate the aphorism that when iron is needed arsenic is indicated, and often iron is contraindicated. Yet arsenic is distinctly a poison and not capable of taking the place of any normal constituent of the body. The writer would explain the paradox as follows: The cases in which arsenic is of especial value are those of chlorosis and of somewhat similar nature, in which there is a failure of general innervation or supply of nerve power, and in which there is a deficiency of hydrochloric acid secretion, with corresponding increase of germ and yeast fermentation. Often the "enterohepatic circulation" (down through the bile passages and intestine and up through the mesenteric and portal veins) drags back with it ptomaines and other toxic substances from the bowel. Now arsenic seems to be directly a tonic to the central nervous system, though how we do not know, and it is an excellent antiseptic. The latter action is, undoubtedly, the principal reason why arsenic allows the body to avail itself of iron present in the food which would otherwise not be absorbed. Some may ask why, if the main action of arsenic is as an antiseptic, some other antiseptic may not act as well. The writer’s answer is that several do act quite as well, except for the apparent nerverine effect. Salol, salacetol, peppermint, wintergreen, or if there is diarrhea, a bismuth antiseptic like the salicylate, subgallate or eudoxine, even lavage or a diet which reduces fermentation, may act very much like arsenic. Indeed, it has seemed to the writer that the value of arsenic in skin affections, especially those like acne, urticaria, and some erythemata which are due to auto intoxication from the gastroenteric tract, depends very largely on its action as a gastroenteric antiseptic. Arsenic should be given with considerable caution, for, unlike iron, it is eliminated to a considerable degree by the kidneys, where its local effect is dangerous. It happened during the writer’s service as interne that a patient developed albuminuria while in the hospital, and the case progressed to a fatal termination from nephritis. As the urine had been several times examined and found normal, careful search was made for a cause. It was then discovered that the patient had been taking arsenic for some weeks, without the knowledge of the attendants. Both visiting physician and interne had been changed within a short time, and through a failure to make proper memoranda arsenic had been continued unduly.

**THE MEDICAL TREATMENT OF APPENDICITIS.**

By HERMAN B. ALLYN, M.D.,
Instructor in Physical Diagnosis, University of Pennsylvania;
Physician to St. Joseph's Hospital; Medical Registrar,
Philadelphia Hospital.

The purpose of the present paper is not to discuss the various remedies and measures which have been recommended for the medical treatment of appendicitis, but to describe, as briefly as clearness will permit, a plan of treatment which I have followed with very satisfactory results for the past three years. This plan consists essentially in absolute rest in bed; in abstinence from food for twenty-four to forty-eight hours; in opening the bowels, preferably by a saline laxative, and in keeping them open to the extent of one or two movements in twenty-four hours.

In common with the great majority of physicians who have been graduated in the last fifteen years, I was taught to use opium in appendicitis, and to use it for its twofold action in lessening peristalsis of the intestine and in controlling pain. I treated cases of appendicitis in that way for a number of years, and have spent many anxious hours in watching over cases, fearful lest they might die, and considering the propriety of a surgical operation. Since opium has been discarded and laxatives employed, the cases have caused me far less anxiety, because there has been less pain, less fever, less tympany and vomiting, and less toxemia as a whole. Moreover, the duration of the illness has been, on the average, shorter.

During the past three years I have had fifteen cases of appendicitis in private practice; all have recovered without operation while under my care. I do not include in this list one case of combined salpingitis and appendicitis, in which disease of the appendix was probably the cause of the disease of the tube, because the disease of the appendix
was discovered only at the abdominal section. The patient made a complete recovery. Nor is any case of doubtful diagnosis, or one remaining still under treatment, included. One case in which an operation was performed after I ceased to be the attending physician is, however, included.

The plan of treatment adopted in these cases was very simple. The patient was put to bed and kept as nearly at absolute rest as the circumstances of the patient and domestic conditions permitted. All food was withheld for twenty-four to forty-eight hours, and water, or some carbonated water, or hot water, allowed very sparingly. By the mouth some laxative was given, preferably a saturated solution of Epsom salt in peppermint water. This is given in teaspoonful doses once in three hours, until one or two movements in twenty-four hours are obtained. In a few instances half an ounce or an ounce of castor oil was given for a single dose, at the beginning of an attack. When the stomach was too irritable to retain the Epsom salt, calomel in divided doses was ordered until the bowels moved once or twice. Occasionally citrate of magnesia is preferable. Neither opium nor morphine hypodermically was given for the pain. In nearly every instance pain subsided when once the bowels had been freely moved, and food had been abstained from. In rare instances codeine was given after the bowels had been moved; but while I am sure that its effects are less depressing and objectionable than those of morphine, I am not so sure that the patient was the better for it. Nevertheless, if an anodyne is to be given in this disease, it should be given after the bowels have been opened. Food was returned to cautiously, a tablespoonful of milk and lime-water once in two or three hours, or what is preferable, a small quantity of beef juice or one of the animal broths, being allowed.

The same methods which have been found useful in the treatment of acute intestinal toxemia in infants are useful in the treatment of many of the cases of appendicitis. This is especially true of the period after the acute symptoms have subsided, and the patient is to be protected by a carefully regulated diet against a recurrence. Pain usually ceases to be a symptom demanding treatment when the bowels are moved once or twice a day; but until that time local measures to relieve pain are very useful. Such agents are turpentine stupes, the hot-water bag covered with a wet piece of flannel, ice, and leeches.

I am well aware that the great weight of medical authority is in favor of the use of opium and against the use of salines in the treatment of appendicitis; though the opium treatment has ceased to be the almost universal practice it was a few years ago. We owe this change of view very largely to the influence of surgeons, who have objected to the use of opium in appendicitis because it masks the symptoms of the disease and may thus deceive them. A more important objection still is that opium aggravates any toxemia that may exist, thus increasing tympany, vomiting, and fever.

The great objection to the use of laxatives in appendicitis has been the fear lest the peristalsis which they cause, may occasion perforation of the inflamed appendix, or exchange a local for a general peritonitis. I cannot say there is no danger of this, but I believe that the danger is exaggerated. On the other hand, in considering too exclusively the possibility of perforation of the appendix physicians have failed to appreciate the bearing of certain obvious facts. In the first place, appendicitis in most instances is not primary, but results from, or is a part of, catarrh of the colon, or fecal accumulation therein; and that an overdistended appendix with occlusion of its mouth will empty itself most readily if the colon is itself empty or nearly empty. Again, the nausea, vomiting, tympany, chills and fever are not, in the great majority of instances, the result of local or general inflammation, but are toxic symptoms, the result of absorption into the general circulation of certain poisons produced at the seat of inflammation or in the neighboring intestine. I believe it is by lessening the general toxemia through elimination of the toxins that laxatives do good in appendicitis. But whatever the explanation may be, in cases treated with laxatives and without opium I have seen less nausea, vomiting, tympany, and fever, and the cases appear to run a shorter course.

Purgation is not necessary. If the bowels are constipated when the patient is first seen, an enema should be given, and then some laxative, preferably Epsom salt, given by the mouth until the bowels are freely moved. Thereafter only sufficient should be administered to secure one or two movements daily.

In speaking of the medical treatment of appendicitis, I do not, of course, mean to imply that the services of a surgeon are not needed. On the contrary many cases are
surgical from the very beginning. My own rule has been to call a surgeon in all doubtful cases. A case in my judgment is doubtful if within twenty-four hours after the patient is seen, or after the bowels have been sufficiently moved, there has not been a decided improvement in respect of pain, vomiting, and fever. In such a case a perforation may exist.

But even the most enthusiastic advocates of operation decline to operate in certain cases. I very well remember on one occasion calling a surgeon in consultation over a case of appendicitis. There was extensive tympany, but only slight fever and a pulse under 100. The aspect of the patient was, however, bad, and the surgeon declined to operate then, believing that if the abdomen were opened the patient would go into collapse and die on the table. He advised the use of Epsom salt until the bowels were freely moved. This suggestion was carried out, and in twelve hours the patient was so much better that it was decided to wait still longer before operation. To make the story short, the patient fully recovered, and then declined operation, until another attack made him again change his mind. It may appear to others as it seemed to me, that if the moderate use of salines will rescue a patient who is deemed so far gone by a surgeon that he would not survive an operation, it should also be a good treatment for milder cases in which the question of operation is never urgent.

AN OPERATION FOR THE CORRECTION OF BADLY UNITED FRACTURE.

BY GWILYM G. DAVIS, M.D.,
Philadelphia.

The patient, a boy aged thirteen years, was referred to me by Dr. Eckman for treatment. Several years ago his left leg had been broken above the ankle and had united at a marked angle. By a recent fall this angle of union had been fractured, and as this necessarily entailed the patient remaining off his feet, it was thought that the opportunity might well be utilized in straightening the limb. It had been broken at the age of eight years by a fall on the sidewalk. He was then treated at one of our prominent hospitals, first with a fracture box and later with plaster of Paris. On removal of the plaster cast the deformity was apparent. He then again entered the hospital, and the leg was rebroken and redressed. After the removal of the dressings for the second time the leg again became deformed.

For the next three years the patient walked about on crutches, when he entered another hospital. The leg was here operated on twice, but the deformity recurred. For the past year and a half he has been walking with crutches, but recently while using a cane he fell and fractured the angle of union.

On examining the limb the deformity was seen to be marked. The seat of the original fracture was at the junction of the lower and middle thirds of the leg. Fig. 1 shows a side view. It is here seen that the two fragments have become united at an angle of forty-five degrees. Viewed from the front the deformity is seen to be just as bad in a lateral direction as in the anteroposterior one (see Fig. 2). The part below the seat of fracture points inward to the extent of forty-five degrees from the straight line of the leg.

To remedy the trouble the following procedure was undertaken: An incision was made on the anterior surface of the leg directly over the apex of the deformity. The bone having been exposed, the soft parts were pushed back and a wedge-shaped piece of bone was removed from the tibia. Sufficient was taken out to allow of a slight over-correction. The divided ends of the tibia were then joined by two sutures of very thick silver wire, the ends coming through
the wound. A short incision was next made on the outside of the leg, over the fibula; this bone was likewise resected and wired with thick silver wire. Owing to the lower fragment of the fibula being fastened in its changed position, it was found impossible to bring it entirely in line with the rest of the bone. Healing took place kindly, the foot and leg being retained in the meantime in a plain tin right-angled splint. The wire sutures were left in about eight weeks and then removed.

It was found that union of the divided bone had not occurred at the site of resection. To hasten its accomplishment and prevent the reproduction of the deformity, the brace shown in Fig. 3 was applied. It consists of two side irons fastened to a steel sole plate in a high shoe, and a sole-leather plate for the front of the leg. The ankle joints of the apparatus were locked by means of a screw placed just below the joint bolt. A piece of sole-leather, strengthened by a couple of strips of steel, was fitted to the front of the leg and fastened by straps to the side irons. This reached from the instep to well up the leg and prevented the leg again bending forward at the site of injury. The ultimate result is shown in Fig. 4.

The interest in cases such as this lies in investigating the causes of the previous failures in treatment and then devising means to avoid them and bring the treatment of the case to a successful end.

The deformity here shown is that which, though in a less degree, most commonly follows fracture of the leg. The heel is drawn up by the tendo Achillis; the foot drops backward, and consequently the anterior extremity of the upper fragment protrudes.

The probable cause of failure of the previous efforts at correction was that the ends of the bone were not brought properly together and kept there until firm union had occurred. Fractures in this location are usually oblique in character, the line running upward, inward, and backward. Many show a tendency for the lower end of the upper fragment to project forward. This is to be met by applying Buck’s adhesive plaster extension to the lower fragment, the leg resting in a fracture box. Three pounds so applied is sufficient. It may be supplemented by division of the tendo Achillis, or a small shot- or sand-bag may be laid over the projecting end of the upper fragment.

The bad results often seen from fractures in this region convince me that the profession generally does not appreciate their importance, or else is unable to apply an efficacious dressing. No pressure should be placed on the leg for six, eight or even more weeks.
after the accident. The pressure of, the weight of the body causes the recently formed callus to yield, and the line of fracture being oblique the fragments begin to slide over one another, and deformity that at first was hardly perceptible becomes, as in this case, very marked. It is to avoid this tendency to overlapping that the ends of the bone in operating are cut square across. Bony union is desired and aimed at, but it may not occur. In this patient it did not occur directly after any of the operations.

It is not necessary to keep the patient abed while waiting for bony union, but it is positively necessary to keep the leg from bending forward at the site of the operation and thereby reproducing the deformity. In this case the greatest efforts were directed to this end. At the time of operation it was found impossible to so extend the foot at the ankle-joint as to make it stand at right angles to the leg. If an attempt had been made to bandage the foot firmly to the foot-piece of the splint it would only have tended to tilt the lower fragment forward and reproduce the original deformity. Therefore, while the foot was left to a considerable extent loose in the splint, the greatest care was taken to keep the tibia absolutely straight. Even after the wires had been removed union was not firm, although the leg was straight. The brace here used was fastened to a high shoe. The various operations which the patient had undergone had shortened the leg. The ankle-joints were made immovable because it was desired to prevent the foot from flexing on the leg, as seen in Fig. 1. The tendency of the leg to bend forward at the seat of fracture was counteracted by placing a thick pad of gauze over the seat of the wound and anterior part of the leg, and then firmly strapping the leather splint on the front, the leather straps being passed around the two side irons. The use of some such apparatus is absolutely essential to the successful treatment of many of these cases.

True bony union was not complete in this case until nearly a year after the time of operation. The eventual result achieved is shown in Fig. 4, taken nearly two years after the operation.

Much depends on the thoroughness with which the bones are joined together. Catgut is entirely too insecure, and my preference is for an annealed silver wire one-sixteenth inch thick. After using the brace for a while the screws locking the ankle-joints are removed and bending of the ankle allowed.

**ERRORS IN THERAPEUTICS.***

* By H. A. Hare, M.D.,
Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

When casting about for some topic which would be interesting and worthy of presentation to your Society, I have come to the decision that I will serve you best if, instead of discussing a single theme during the time given me, I take up several topics which are of more or less interest to very one of us, be his practice what it may; for we are met together in order that by comparing views we may gain information which will prove of value in our daily rounds. Often it is as well to take a view of what has been done as to attempt to find our way into new fields in which the paths have not been well enough trodden to be safely followed.

With your permission, then, I shall ask your attention first to a consideration of the value of the iodide of potassium or sodium in the management of cases of chronic renal disease. Aside from the mere empirical use of an iodine compound we must discover whether its employment can be based on rational grounds, then determine how it may do good, and finally consider whether conditions may exist in which it can do harm.

It is manifest at the start that we must separate the parenchymatous nephritis from the interstitial type, for the two states are pathologically and symptomatically widely at variance.

Taking the interstitial variety first, we find that there are three indications to be met in the care of patients suffering from this disease, namely, to diminish the call upon the excretory power of the kidney, to lower arterial pressure and thus relieve strain upon the heart, and finally to treat complicating states which cause the patient to be in danger or distress. It is evident that the iodides do not decrease but rather increase the excretory work of the kidneys, and this being the case, is there any reason to suppose that the iodides can be of any value so far as any direct influence upon the renal lesion is concerned? An examination of the lesions found will, I think, bring forth a negative reply from the most enthusiastic therapeutist. Whether we believe in the old theory that the increased growth of the connective tissue causes pressure on the parenchyma

* Part of the Address in Medicine before the eightieth anniversary of Cumberland County Medical Society of New Jersey, December, 1898.
with resulting wasting of this part of the kidney, or whether we adhere to the newer pathological view, which is probably correct, that the overgrowth of connective tissue is a secondary process, long experience tells us that connective tissue already formed, particularly if its formation has been gradual and definite, is not capable of absorption or material modification by any treatment we can institute; and the older the patient the more certain is this view. As interstitial nephritis is a disease of advanced life regenerative changes are impossible. So far, then, as a causative agent, in the sense that existing damage can be repaired, we can cast the iodides aside. To quote from Furbringer's essay, we know of no specific drug capable of arresting the process of contraction. He agrees with Cantani that the iodides are without effect unless the nephritis is syphilitic in character, and that their use simply tends to produce dyspepsia and headache.

When we turn to the side of preventive medicine the aspect of the case is quite different, for while chronic interstitial nephritis is an insidious malady, it is after all but a manifestation of a number of conditions associated with general or local conditions of perverted nutrition and metabolism, and the iodide by exercising an influence upon cell growth which we call alterative so modifies the abnormal state that the exciting cause of renal change is put aside or held in abeyance. We find, therefore, that the iodine compounds can only be expected to help the patient when it is clear that by their use we can remove the cause of the renal change. Under what circumstances can this result be expected? To take up the least frequent cause, we find that in that form due to lead the iodides so aid in the elimination of the poison from the body that they exercise a very powerful effect for good aside from any alterative function. So, too, in syphilis the direct influence of the drug upon the course of the disease renders it of great value to prevent further evil changes. In the chronic renal and vascular changes due to lithemia and gout they are also of value, since they are known to modify the severity of these dyscrasias; but in a very much larger class of patients these causes are not active, and the cirrhotic process seems to be a degenerative change due to old age, which may be reached at an unusually early period of life. Of how much value are the iodides in this class in which we know not what is the real proximate cause, and to which we cannot direct the use of the iodide with any clear idea of its possible action? I believe very little good can come directly from its employment, for I do not know of any researches that show the iodide to exercise an inhibitory influence on a cirrhotic process produced, unless it is produced by a cause relieved by the iodide. What, then, shall we decide as to the use of the iodides in renal cirrhosis? The answer would seem to be that they should be employed because of their specific power in some cases, as those due to lead, syphilis, and gout, and on general principles in those cases in which these factors are not manifest either because they are obscure or because by their influence they lower arterial pressure and so relieve the heart of the burden of working against a great *vis a poute*, causing a simultaneous decrease in the symptoms of headache, dizziness, or vertigo.

Having found that there are good reasons for the use of the iodides, are there any reasons which will make it unwise to employ them in interstitial nephritis? The reply to this question depends to a great extent upon the dose which is employed and preparation used, because if very large doses of the potassium salt are given we get a powerful influence along with the effect of the iodine. It is not generally recognized that potassium is a powerful depressant poison which is largely eliminated by the kidneys, and which is therefore retained in the body in a malady like that we are discussing owing to the impaired function of the kidney. In many of these cases marked degenerative changes are present in the heart muscle, and the potassium still further depresses this feeble viscous. The use of the iodide of potassium should therefore be cautious and in small dose in interstitial nephritis, and the same rule applies in less degree to the iodide of sodium and strontium. What remedy of a distinctly alterative type may then be more freely used? The reply to this is that the protiodide of mercury and the bichloride are more useful and less dangerous, since they do not exercise a general depressant influence over the heart muscle or the body protoplasm in general, nor do they load the body with a large amount of inorganic material which must be eliminated.

Finally, let me reiterate the fact that the iodides when used in cirrhotic states due to syphilis only act as prophylactics against the further progress of the malady and in no way clear up the results already produced.

In regard to chronic parenchymatous neph-
ritis it is, I think, a fairly well decided point in medicine that the iodides are not only valueless but harmful. The renal lesion is not one in which the action of one alternative can be of much service; the glandular apparatus is so diseased that the iodine and potassium are not eliminated, and the former drug may produce renal irritation in the still active secreting portions of the kidne and so speedily produce fatal conditions. In reply to a question as to the wisdom of using the iodide, Dr. Tyson replied to me that he thought it necessary to use great caution in cases of the parenchymatous form, in which a hypersensitiveness to this drug often exists. In other words, the underlying causes of chronic parenchymatous nephritis and the pathological process itself are such that the action of an iodine compound cannot be advantageous.

There are two other remedies which are abused in renal disease, namely, iron and opium, which have become popular probably because we have recognized that we are face to face with an incurable disease and grasp at straws in the hope of saving the drowning man. On the other hand, we know that in many cases by proper treatment we can so modify the course of the malady and control its symptoms that life may be greatly prolonged. Here again we must separate the two general types of kidney disease if we are to obtain clear ideas of the effects of iron.

In interstitial nephritis there is no reason why this drug should be given except in rare instances, for it has no direct renal influence, and whatever advantage follows its use is to combat anemia, a condition not well developed in most cases of interstitial disease. Further, it increases the headache, so often a pronounced symptom of high arterial pressure, disorders the digestion, and accumulating in the body acts as a burden upon the tissues. It should not be used unless there is a distinct reason for its employment.

Even in the parenchymatous form of renal disease its use is far more limited than is generally understood, for here again it cannot influence the pathological process in the kidney. In other words, as a result of the toxic matters which accumulate in the blood in this malady degenerative changes take place in it and anemia develops, and this anemia may be well combated with iron; but beyond the relief which it may render in part to the anemia, there is no evidence that it exercises any effect of value on the kidney itself. Further, there are cases of parenchymatous nephritis in which anemia of any degree is not present and yet in which iron is prescribed. In other words, by a curious process of transition the profession has mentally transferred the value of iron from the effect to the cause, or in other words used a remedy for a symptom as a remedy for a disease. Not only is this a scientific mistake, but it is a practical blunder, since iron is often deleterious in its effects in these patients. As we all know, it tends to cause constipation, a condition the reverse of that desired in a body which needs active bowel movement to aid in the elimination of poisons. If constipation exists fluids which should be passed out by the body go to aid in the production of dropsical effusions. Again, iron often causes headache of a congestive type or other signs of cerebral congestion, and this state is also the antithesis of that desired in renal disease. Finally, it tends to produce a disordered digestion, and is only needed in the body in minute quantities, there being but thirty-two grains of iron in the entire body, whereas as much as this is often prescribed in a few days.

The subject has been well discussed by Dr. Tyson in one of his recent papers, and he has done a service in directing attention to a subject in which the profession has been guilty of rank empiricism. I may well be asked why it is that this drug has attained such a wide-spread use in practise if so little can be said in its favor, and why it is that some of my audience have seen benefit credited to the iron. This is proved by the fact that iron is nearly always given in the form of the liquor ferri et ammonii acetatis, and it is the acetate of ammonium rather than the iron which produces the diuretic influence which we seek in this disease when the urine is scanty. There may be cases needing iron. If so, why not give it, to use a pharmacopœial phrase, in a more elegant and agreeable form instead of this bulky liquid, and if a diuretic is needed why not employ some diuretic which is more certain and active? Among French clinicians the sugar of milk in drachm doses is used, and while others give caffeine or its cousin theobromine, some give digitalis. For many years irregular and regular practitioners have used another drug which has not attained the reputation in this part of the United States that it deserves, namely, Apocynum cannabinum, or as Rush called it, the "vegetable trocar." One reason for this has been the fact that confusion as to the real Apocynum
has existed even among pharmacists, and *Apocynum androsaemifolium* has often been dispensed with no results or only harmful ones. There is no doubt that in the scanty urinary flow of this form of renal disease with dropsy this drug, in the dose of five drops of the fluid extract three times a day, gives very extraordinary results in relieving dropsical effusions.

There is another drug which is constantly given in nephritis without clear ideas as to its exact effects, namely, opium. Its use in ordinary forms of renal disease without cerebral or nervous symptoms is certainly not necessary and leads again to the retention in the body of effete materials which should be eliminated. When we come to consider its use in convulsive uremia we find contradictory evidence concerning it, some asserting that it is a very useful drug and others that it is worse than useless. One of the strongest upholders of its value in uremic convulsions was Loomis, but he was careful to limit its use to the uremia of acute nephritis and did not commend its employment in the uremia of chronic nephritis. This is a fact not generally known. One can understand that a drug might act well as a nervous sedative in a condition in which a poison had produced acute nervous excitement, and fail to so act in a state in which nervous excitement was only a result of prolonged intoxication. In the latter cases opium would seem to be a dangerous drug. It must be evident to those who have seen different cases of uremia that the symptoms arise from different poisons. Sometimes these poisons cause stupor without spasm, in other instances they produce violent convulsions because the cerebral cells are primarily diseased, or because the poison in one case is irritating and in another sedative, and therefore opium might be useful in one case and harmful in another. These facts have been well dealt with in the paper by Tyson which I have quoted. Speaking of interstitial nephritis, he says: "I regard the use of morphine in such cases as harmful in the extreme, and its hypodermic injection should be positively forbidden. It causes a decreased urinary flow, suppression, coma, and death. This is particularly true of old persons."

Not long since I asked the following question of several well known practitioners: Have you found that the existence of chronic parenchymatous or chronic interstitial nephritis renders it necessary to use caution in the use of opiates? To this question Dr. Tyson answered, "Yes, especially chronic interstitial nephritis." Dr. Da Costa says, "Yes, I share the common opinion that it necessitates caution;" and Dr. Musser, "Yes, particularly if there is an associated pulmonary complication, as congestion, pneumonia, or bronchitis, and very necessary if the tendency of intercurrent process is to lead to dilatation of the heart and secondary renal congestion." Further, Wood tells us that his own belief is that whenever the kidneys are seriously diseased the physician should be exceedingly careful in the administration of opiates, because the chief channel through which these are eliminated is choked up. Still more recently, however, Ringer has urged the use of morphine in uremic spasm.

Here again I fail to see any possible benefit to be derived from opium that cannot be obtained by the use of other drugs more directly anticonvulsive and less stuporous in their effects, such as for example as chloral and the bromides, and for the convulsion itself either by the mouth in full dose, or by inhalation, or hypodermically, since it will act as a venous sedative and is said to have a peculiarly beneficial effect in uremia. Nor should the great value of injecting normal saline solution into the veins or the subcutaneous tissues be forgotten. Of this I have already written in several addresses.

Finally, a word as to pilocarpine in uremia. Originally heralded as a remedy for uremia, it has at last fallen into deserved disuse, for while it sweats the patient it lowers circulatory integrity and so indirectly aids in producing that most to be dreaded complication, pulmonary edema. Further, it also tends to fill the bronchial tubes and all the air-passages with liquid secretion, and so hastens the increasing dyspnea and cyanosis. I believe that pilocarpine is contraindicated in uremia as a rule, and absolutely harmful in any case in which the heart is impaired or the lungs not normal; and what cases of uremia are lacking in these two objections? In eclampsia, which is after all a form of uremia, obstetricians seem as a unit against its use.

Perhaps the thought has entered your minds before this that this is a curious occasion, in that a professor of therapeutics in a great school is hurling denunciation at well recognized therapeutic practices and posing as a therapeutic nihilist; but this he is not doing. A good hunter is one who knows when and where to shoot, and a careful physician knows when to use certain remedies and when to avoid them.

THE PERVERTED INTENT OF PATENT LAW.

The American people are wont to consider
that in practically every respect they are in
advance of their more unfortunate brethren
who are thought to suffer from a mon-
archical or paternal form of government, and
they believe that by legislating for themselves
they obtain the best results. In some re-
spects, however, they fail to receive certain
benefits which accrue to those who are sub-
jected to more paternal laws, and in no in-
stance is this more noteworthy than in the
case of drugs which are made under patents
and which are sold in this country at prices
far in excess of their real worth. The Octo-
ber number of the Bulletin of Pharmacy con-
tained an interesting editorial dealing with
this important matter. Few physicians and
none of the laity are aware of the fact that
phenacetin sells in Canada at 25 cents per
ounce, but for $1 in the United States; that
alcoholin sells in Canada for 20 cents and
for $1.35 in the United States; and that trino-
inal sells in Canada for 90 cents and at $1.50
in the United States. These are but a few
of a large number of synthetic chemicals
which are sold throughout the length and
breadth of the land at similar rates. The ques-
tion at once arises, why is it that such enor-
mous prices, far above any justification, can
be imposed upon the American people? and
the reply is that we have such patent laws as
are not permitted to exist in Germany,
France, England, and Canada. In those
countries the law is such that no exclusive
monopoly in a remedial substance is possible,
and in Germany in particular it is not possible
to patent a food or a medicine, but only
the process by which it is manufactured, the
result being that others can frequently pre-
pare these substances by other processes, and
thereby two results are obtained: first, ex-
tortion is avoided, and second, chemical
investigation is stimulated. In the United
States, on the other hand, we grant (a) a
patent on the process, (b) on the substance
itself—that is to say, on its chemical com-
position—and (c) we allow the name to be
registered, thereby rendering the name the
exclusive property of the manufacturer for
time, even though his patent may expire.
So strict is the American law that the same
product may not be manufactured by a dif-
ferent process even though offered for sale
under a different name.

Action has recently been taken by the
American Pharmaceutical Association look-
ing towards the revision of the law dealing
with these products, and the President of the
United States has recently appointed a com-
mission composed of the assistant commis-
sioner of patents at Washington, Mr. Arthur
Greeley, Judge Peter Grosscup of Chicago, and
Mr. Francis Forbes of New York City. We
would suggest to our readers that through
their representatives in Congress or by direct
communication they impress upon the Com-
mssion the necessity of revising patent legis-
lation. It is a monstrous wrong that substances
capable of so much good can only be obtained
at such outrageous prices, far in excess of the
reward due to their inventors or manufac-
turers. Such profits should be prevented by
laws as strict as those which forbid rates of
usurious interest.

THE ERUPTIONS PRODUCED BY
CHLORAL.

In addition to the nausea, vomiting and
purgation produced by chloral in some patients
through its irritative action upon the stom-
ach, and in addition to the coryza which it occasionally produces, chloral is capable of causing other effects, aside from any depressant influence which it may exercise upon the circulatory and respiratory systems. Within the last two years we have called attention in these pages to the frequency with which drugs produce lesions in the skin, the cause of which is frequently not recognized, and these lesions are therefore very obstinate under ordinary treatment until by chance the use of the drug which is causing them is stopped. In this connection we may call attention to an interesting paper which has recently been published by Labadie-Lagrange, of Paris. In the first of his cases a girl of seventeen without any antecedents of note was seized with fever, sore throat, and an eruption upon the arms of a diffuse red character, with tiny punctated marks. The diagnosis was that the patient was suffering from scarlet fever, and the condition of the tongue was thought to be characteristic of this disease. The tonsils were covered by a gray, gangrenous-looking exudate. There was no albuminuria in the urine and the lungs were clear. The diagnosis was that of ordinary scarlet fever with gangrenous tonsillitis. The temperature curve was of ordinary scarlet fever. Two days after the patient was seen the eruption faded and the temperature fell by lysis. Frequent applications of antiseptics were made to the buccal mucous membrane of a lotion of salol and camphor, and to the skin chloralized vaselin was applied. After this treatment had been continued for a considerable period of time, desquamation of the skin having been persistent, although it was limited by the use of the chloralized vaselin, the temperature suddenly rose several degrees, and at the same time a curious rose rash developed upon the upper and anterior portions of the thorax and in the dorsolumbar region. This eruption was accompanied by a disagreeable sensation in the skin, and finally was followed by little papules which were surrounded by a red areola. Labadie-Lagrange believes that this secondary eruption was due to the chloral applications. In a second case in which chloral was applied locally similar symptoms were developed, namely, an erythematous rash, characterized afterwards by a papular eruption.

It is true that in these instances the eruption occurred from the local application of the chloral rather than by its internal use, but that eruptions do occur when chloral is used either internally or externally is well known. They have been reported by Schüle, Fuller, Brown, Mayer, Martinette, and Curran, and in America by Dr. Morrow in his well known book on “Drug Eruptions.” Chapon in a Paris thesis of 1894 described such a condition.

Mason recorded three cases of measly eruption which lasted three or four days, and Burham has noted scarlatiniform eruptions after the use of chloral. In Brown’s cases curious red patches appeared over the malar bones, and across the bridge of the nose. Mercier has seen an urticarial rash, and if a large amount of literature were to be searched it would be found that chloral has been shown to produce almost every variety of lesion of the skin which is not dependent upon an infection and a microorganism.

Two theories have been advanced to explain these eruptions. One is that the drug produces an angioneurosis or vasoparalysis, probably by an action on the vasomotor centers. The other theory is that some of the chloral is eliminated by the glands of the skin, and in its elimination produces local irritation. According to Aviragnet these eruptions may be divided into two great classes. In the first they appear in the presence of conditions of the nervous system characterized by exaggerated excitability, as for example, chorea, insanity, tetanus, general paralysis, also in transverse myelitis and after operative shock. In the second class of cases they occur in instances in which there is retention of chloral in the system, as for example, in acute and chronic enteritis, eclampsia, hepatic disease, advanced tuberculosis, and abdominal tumors. Then, too, it is well known that the simultaneous administration of alcohol with chloral often causes dermal manifestations, and hot drinks given with chloral, particularly if they are copious, are apt to produce such effects. Of course, in the cases where chloral is applied externally it produces a direct local irritant influence.

THE NEW TREATMENT OF HEMORRHAGE.

There are certain hemorrhages which, even though they are profuse, can be readily controlled because they occur in places where mechanical means can be employed for their arrest; but there are other hemorrhages which spring from vessels so deeply situated that
compression and ligature do not suffice to control them, and in their presence the physician only too frequently finds himself unable to do much for his patient. In this connection the papers which have been recently published in French literature concerning the value of gelatin and calcium chloride or gelatin and sodium chloride for the purpose of causing coagulation of the blood are of interest, and some of them have been accorded space in our Progress columns.

One of the most recent of these papers dealing with the indications and contraindications to hemostasis caused by the action of gelatin is that of Paul Carnot in *La Presse Médicale* of November 16, 1898. After calling attention to the fact that he made his first communication concerning this subject in 1886, he goes on to mention the hypodermic injection of sterilized gelatin solutions for the purpose of increasing coagulability of the blood in general. He then points out that the local use of these solutions is exceedingly valuable in controlling capillary or oozing hemorrhage where compresses fail to produce the results desired, and that this substance often suffices when preparations of the iron and the acids fail. It is, of course, absolutely essential that the solution when it is injected shall be absolutely aseptic. Very commonly the gelatin has been dissolved in ordinary sea-water which has been filtered and sterilized. In other instances it is, as we have already indicated, dissolved in ordinary water to which calcium chloride has been added, calcium chloride having great power, as first pointed out by Wright, of Netley, England, in increasing the coagulability of the blood. The solution that Carnot has employed among others is one composed of gelatin 12 drachms, chloride of calcium 2½ drachms, and water 1 quart. Queyat has modified this to the extent of adding a small quantity of glycerin to the solution. Any advantages this glycerin may have as a solvent are, we think, more than counterbalanced by its physiological action, which ought really to contraindicate its introduction into a mixture designed for subcutaneous injection.

As the solubility of the gelatin is a good deal increased by the application of heat, and as heat also aids in making it fluid, it is well to sterilize it immediately before it is to be used, and then to employ it before it becomes thickened by cooling, care being taken of course that it is not used so warm as to cause damage. It is claimed that when one to two ounces of this solution is given under the skin into the loose subcutaneous tissues of the back or thighs it acts very speedily in causing coagulation at the bleeding point. When gelatin solutions are applied to exposed bleeding surfaces, care should be taken to protect these areas lest putrefactive changes take place in the gelatin after it is applied, and if the gelatin solutions are used in the nasal cavities to stop hemorrhage, such precautions must be carried out. Carnot then goes on to point out that there is some danger of producing hypercoagulability of the blood if the gelatin solutions are used too freely, and this possibility is to be considered as an argument against its too free employment. Indeed, Carnot believes that the free injection of both the gelatin and calcium chloride in the presence of pressing hemorrhage may, though it controls the hemorrhage, ultimately exert a deleterious influence upon the blood in general. In his opinion, therefore, the subcutaneous use of this mixture has certain disadvantages and ought not to be commonly resorted to. He thinks that the gelatin solutions are of the greatest benefit when applied locally, and that when it is necessary to give a hemostatic hypodermically calcium chloride itself should be employed, as under these circumstances it is effective in aiding in the coagulation of the blood, but is not capable of causing hypercoagulability since, as is well known, calcium chloride when given beyond a certain point ceases to increase the coagulability of the blood and rather tends to exercise an opposite influence.

In this connection Deguy tells us in the *Journal des Praticiens* of November 12, 1898, that the subcutaneous injection of gelatin solutions is capable of producing the following disagreeable symptoms: A condition of fever may develop, ranging from 2° to 3° above normal, and this may last for a day or two. It is apt to be present in the evening and not in the morning, and sometimes is accompanied by chills and insomnia. The local accidents which follow its injection may be divided into three parts: Pain, due to the injection, of a burning character which is increased by pressure; second, a diffuse redness of the skin or pseudoinflammatory process, violaceous in appearance, which appears for a moment on pressure and then immediately returns; third, a diffuse induration of the tissues, having very much the same sensation as the induration due to anthrax. Usually this lasts a number of days.
From what has been said for and against this method of using gelatin it is evident that it may prove to be not so valuable a hemostatic as we were led to believe when its usefulness was first suggested; or rather, to express it otherwise, the untoward effects of this treatment may more than counterbalance the good which it is capable of doing.

THE ABUSE OF REMEDIES.

In the recently published edition of a book on Therapeutics by the editor of the Gazette the following motto appears on the front page: "When called to guide a patient through an illness the physician should be a watchman all the time and a therapist only when necessity arises." That this is a correct interpretation of the duty of the physician is without doubt, and yet there are few physicians who follow its teachings, partly because they overlook it and partly because the patient expects active interference in his behalf and regards a failure to order some medicine as an evidence of lack of interest on the part of his attendant. This desire that a malady should be attacked and vanquished as rapidly as possible is most natural, and no class of patients are as restive under lack of treatment as physicians themselves when they are ill. Probably no class go from one remedy to another without giving the first a fair opportunity to do good more rapidly than physicians, and for this reason, if for no other, they should be patient with those who consult them. Now it is a well recognized fact in the case of the infectious diseases which are self-limited that do what we will we cannot abort them, although we may modify the severity of their effects on certain parts of the body; yet it is the invariable custom with the greater part of the profession to begin active dosing at once, when as a matter of fact this is entirely unnecessary. In addition to the reasons already stated for this act there is the additional reason that they have learned that this or that practice is followed by this or that authority, and they follow blindly in his footsteps, failing to note that the treatment he suggests is only to be employed when needed and not all through the illness.

At the present time there may be said to exist two classes of writers on therapeutic topics, namely, those who believe in giving remedies all the time and claim that they get good results, and those who, having studied with care the whole realm of therapeutics, recognize that there are what may be called limitations to treatment, and that oftentimes it is well to let the vis medicatrix naturae have an opportunity of bringing about recovery, always recalling the fact that all our measures must be aids to this force and that if a drug opposes this force the effects are disastrous.

A good illustration of the administration of a drug for the relief of a condition, and an example of the damage which that drug is capable of producing, is the employment of chlorate of potassium internally in the treatment of diphtheria and membranous croup. This substance has very little germicidal power, practically no influence upon the false membrane, and a comparatively feeble influence upon the mucous membrane itself. On the other hand it is, next to the cyanide of potassium, the most poisonous of the medicinal potash salts. It is irritating to the kidneys, breaks down the blood and interferes with its oxygen carrying power, and yet for a generation this substance in one form or another has been poured into the stomachs of children whose kidneys were already breaking down under the work of excreting the poisons which were accumulating in their blood. Similar remarks hold true, but with somewhat less force, concerning the routine use of coal-tar products in all infectious fevers, in connection with the use of opium in certain forms of Bright's disease, and finally our attention has been called to a case of poisoning by chloroform which has recently been reported in one of the medical journals, in which the author after describing his treatment is frank enough to add these words: "It was nearly two days before the patient recovered from the effects of the drastic measures instituted to save her life." This statement is the more noteworthy since from the description of the case the patient was at no time exceedingly dangerously ill, although sufficient strychnine was given to produce at the end of an hour signs of strychnine poisoning. Notwithstanding this fact more strychnine was given. It is not often that one is conscientious enough to make such a report about a treatment which he has instituted, but it is well for us all from day to day to look back over our cases and to analyze our treatment of them with the object of discovering, first, whether everything that we have prescribed was absolutely needed, and second, and more important, whether anything that we prescribed did more harm than good.
TREATMENT OF WOUNDS OF THE
THORAX.

In view of the progress made in abdominal
surgery and the very definite rules laid down
and generally accepted in regard to non-
penetrating and penetrating wounds of the
abdomen, it seems singular that the teaching
concerning wounds of the chest is, with the
exception of the modifications incident to
antiseptic surgery, very much the same as
that which was accepted twenty or thirty
years ago. Nor have there been collections
of cases, nor reports of individual experi-
ences, nor collective studies upon this impor-
tant subject even remotely commensurate
with those which have marked the medical
literature of abdominal lesions. In this rela-
tion a communication of Klett (Deutsche
Zeitschrift für Chirurgie, October, 1898),
based upon Burckhardt's experience with
eighty-six stabs and twenty-four gunshot
wounds of the chest, is instructive. In our
Civil War eighteen bayonet wounds of the
chest were reported, with nine deaths. Prahl
collected forty-two wounds of a similar nature
inflicted during war, twenty-two of which
ended fatally. There were seventy-eight
spear wounds of the chest reported in the
German army between the years 1888 and
1896, only eight of which were penetrating.
Two of these died because of wounds of the
heart; two were invalidated because of subse-
quently pleurisy. The other four recovered.

The mortality of gunshot wounds of the
chest collected from reports of the various
wars in recent times is 27.5 per cent, and is
about the same for the wounds inflicted in
peace either accidentally or intentionally.

The treatment recommended by Burck-
hardt is one which commends itself as in
accordance with the general principles of
surgery as practised to-day. All stabs,
whether penetrating or not, are enlarged
under ether layer by layer until the pleura
is reached, thus converting the puncture into
an open wound and enabling the surgeon to
thoroughly cleanse the tract.

In the majority of instances the wounds
inflicted in peace are by means of thoroughly
infected instruments, as for instance pocket-
knives and ice-picks, and a fairly large pro-
portion may be expected to suppurate. This
infection is likely to extend from the parietes
to the pleura itself, and to be followed by a
secondary empyema. Exploration also en-
ablesthe surgeon to determine whether pariet-
al vessels, such as the internal mammary or
intercostal, have been wounded, and thus to
avoid the dangers of fatal primary or con-
secutive hemorrhage. Unless large blood-
vessels have been cut the wound of the lung
can usually be left to itself.

In the case of gunshot wounds Burckhardt
simply cleanses the orifices of entrance and
exit, since he holds that such wounds are
less likely to become infected than those by
steel. There seems no good reason, how-
ever, why the general principle of explora-
tion should not be carried out here, since
dangers of hemorrhage are quite as great as
in the case of stab wounds, and since thus
can be obviated the possibility of a general
emphysema.

Of the eighty-six stab wounds treated by
Burckhardt, thirty-two were penetrating;
twenty-eight of these were converted into
incised wounds and were thoroughly disinf-
ected; twenty healed promptly. In one case
pericarditis developed, in one case pleuritis,
in one hemotherax, and in five empyema,
which required a secondary operation for its
cure. All patients were finally discharged
well.

In four patients the primary disinfection
was omitted. One healed promptly, two suf-
f ered from empyema, the third died from
infection which started along the track of the
wound, and the fourth recovered after an at-
tack of pleurisy.

Of the twenty-four gunshot wounds treated,
two died as an immediate consequence of
extensive injury; a third patient died on the
twenty-eighth day after complete healing, of
fatty heart. Of the remaining twenty-one
cases, fourteen showed absolute signs of
wound of the lung. They all got well; six,
however, suffered from pleurisy, two even
required drainage. One suffered from peri-
carditis, and was later on treated for empy-
ema.

In sixteen cases the position of the bullet
remained unknown.

A further investigation as to the after-history
of these cases showed they regained their
health completely and were able to perform
even arduous work.

This important communication, based as it
is upon a very large individual experience,
appears shows that the common practice
of at once applying an aseptic or antiseptic
occlusion dressing to penetrating or non-
penetrating wounds of the chest is a pro-
cedure which should be adopted only when
the patient is so placed that he cannot be
operated upon under circumstances of proper
surgical cleanliness. It would seem that all wounds should be explored down to the pleura and should be thoroughly cleansed and drained, and that an effort should be made to discover whether or not parietal vessels are bleeding.

Reports on Therapeutic Progress

THE TREATMENT OF RHINOPHARYNGITIS IN CHILDREN.

The Journal de Médecine de Paris of September 25, 1898, recommends the following treatment: The nasal cavity should be sprayed by the following solution, or solid vaselin may be employed and the ointment introduced into the nasal spaces:

B Antipyrin, 7 grains;
Vaselin, 6 drachms;
Boric acid, 1 drachm.

In other instances, where the child objects to this treatment, the following may be used:

B Menthol, 1 to 3 grains;
Olive oil, 2 drachms.

This mixture may be dropped into the nose.

In instances where secretion is chronic and profuse the following powder may be placed in the nasal cavities:

B Aristol and lactose, of each 1 drachm;
Aceto-tartrate of aluminum, 1 drachm.

It is well at the same time to wash the nasal mucous membrane once or twice a day with hot water containing boric acid, or salt, or one of the natural saline waters. Where the glands are torpid and the secretion is tough and chronic, the following liquid may be applied to the pharyngeal wall:

B Powdered iodine, 3 grains;
Iodide of potassium, 30 grains;
Glycerin, 1 ounce;
Essence of peppermint, 4 drops.

CHLOROFORM ANESTHESIA.

Many years have elapsed since the Hyderabad Commission undertook its well-known inquiry into the action of chloroform vapor, and since then the subject has been widely and incessantly discussed. Notwithstanding the great amount of interest that has been excited by the subject, and the large amount of energy that has been displayed by those who have taken part in the inquiry, it can hardly be said that our knowledge of the action of chloroform has been advanced to any appreciable degree, nor that any of the points at issue have been settled.

Chloroform continues to claim as many victims as of yore, and its use as an anesthetic has, in some quarters at least, been more loudly condemned than ever. Moreover, the diversity of opinion regarding the best method of administering the anesthetic appears as remarkable as ever.

The confusion which surrounds the subject becomes daily more embarrassing to the surgeon who has much operative work to perform. On the one hand he is met with the difficulties and restrictions of ether anesthesia, whilst on the other hand he is confronted with the supposed dangers of chloroform. He is assured by one authority that the use of chloroform as an anesthetic is entirely devoid of danger, whilst others, who claim equal experience, maintain that its use is almost criminal. There is little doubt that one explanation of the meager results which have followed this inquiry is the fact that the discussion has, from its commencement, been carried out in a spirit of such violent controversy that it has tended from time to time to lapse into a mere exchange of personalities.

The unfortunate introduction of the controversial element into the discussion has tended not only to clog the progress of the investigation, but has also served to obscure the issue, and divert the course of inquiry into channels of minor importance.

One of the most remarkable points connected with the subject, and one which has hitherto received but little attention, is the fact that chloroform anesthesia is carried out with such remarkable success in India and with an immunity from fatal results unknown in England or America. Hardly a week passes without the record appearing in one of the English medical journals of one or more deaths from chloroform, yet the pages of the Indian Medical Gazette for the past ten years contain reports of only three fatal cases. It is quite possible that other cases may have occurred besides those which have been recorded, but the proportion of such unrecorded cases is probably quite as great in England and America as in India.

The comparative safety of chloroform anesthesia in India is a fact which merits the closest inquiry, and we believe that such an investigation would be likely to produce more fruitful results than some of those others which have been undertaken in the past few years.

The conditions under which chloroform is used as an anesthetic in India differ very widely from those which exist in England.
In the first place, as the operation is conducted with open windows and doors, the air which the patient breathes is much purer, and the percentage of carbonic acid gas is very much less than it is in colder climates. In the second place, the temperature of the air is very much higher as a rule than in England, and evaporation proportionately increased. It is quite conceivable that both these conditions should have the effect of minimizing the danger of chloroform anesthesia.

Another factor which possibly may have a favorable influence is the fearlessness of the natives of India in regard to the effects of chloroform. The ignorant classes in India, who form such a large bulk of those treated in hospitals, seldom exhibit anything like the amount of fear of the anesthetic which is so common amongst English people; a fear which in the latter case is justified by the frequency of fatal results in their country. In England there are probably few persons who have not had personal knowledge of some fatal case, whilst in India the opposite is the case.

We draw attention to these facts as affording indications as to the direction which such an inquiry should take. There are doubtless many other circumstances which share in producing a condition more favorable to chloroform anesthesia as practised in India.

We believe that an inquiry into the matter would prove of great value, and we trust that ere long some one may be induced to undertake an investigation of this nature.—Indian Medical Gazette, June, 1898.

**THE ACTION OF THYROID AND PARA-THYROID EXTRACTS UPON METABOLISM IN THE INSANE.**

This very important topic is discussed by Easterbrook in the London *Lancet* of August 27, 1898. He first proves that the thyroid is a profound catabolic stimulant. With the patient at rest in bed and on a fixed mixed diet there is a great increase in all the excreta, especially in the water and carbonic acid, and to a less extent in the urea and other products of nitrogenous metabolism. Thyroid thus greatly accelerates the splitting up and oxidation of the tissues. The fats of the tissues suffer most severely, and the reason is probably simply this—that the fats are the most fluctuating of the tissue substances; they are the most readily formed and the most easily lost of the body stuffs, consequently when a powerful catabolic stimulant such as thyroid is introduced into the system the fats are the first to be burned up, and when the thyroid becomes eliminated from the system fat is rapidly laid on. Amongst the fats thus affected are probably the so-called “azotized fats,” or phosphorized constituents of the central gray matter, and the early excess of phosphoric acid in the urine is probably derived from this source. The tissue carbohydrates are probably also considerably oxidized, and although the clinical proof of this is not so clear, the great muscular weakness and incapacity for physical exertion during thyroidism may indicate that the glycogen in the muscles, which is the chief immediate source of muscular energy, has been largely burnt up and so is not available. The tissue proteids are also excessively wasted, the “unorganized” proteid being probably affected first, and finally the living proteid or bioplasm itself. After the thyroid is eliminated from the system a gain in weight sets in, and there are other evidences of a powerful anabolic reaction. The rationale of this change seems to be explainable by Hering’s theory of the “internal self-adjustment of bioplasm,” according to which the bioplasm, when it is being catabolized by some stimulus (e.g., thyroid), tends less and less towards catabolism and more and more towards anabolism, which sets in with a rebound as soon as the catabolic stimulus is removed.

As to the channels by which the thyroid reaches the tissues, the changes in the blood during thyroidism probably indicate that the drug is distributed by the blood to the tissues, but at the same time the early occurrence of the sensory motor and mental phenomena during thyroidism, the evidences of hyperactivity of the central gray matter followed by the signs of its exhaustion, and the early increase of the phosphoric acid in the urine, all seem to the writer to indicate that the thyroid specifically stimulates the central nervous system and through it the metabolism of the tissues. In direct support of this Easterbrook mentions that he fed two rats upon porridge and water, but to one of them was also given daily one thyroid tablet. The thyroidized rat died with tremors and other nervous symptoms on the fourth day, and while the brain cells of the healthy rat were normal in appearance, those of the thyroidized rat showed distinct chromatolysis, many of the cells being “ghost-like.”

Finally, a word in explanation of the conflicting results of the removal of the thyroid
and parathyroids. There seems to be a strong similarity between the "tetanic" symptoms which follow parathyroidectomy, the acute "neurotic" symptoms which follow thyroidectomy, and the toxic phenomena of thyroidism. It would seem that the essential result of thyroidectomy is an artificial myxedema (Horsley's "mucinoid" and "masrasic" stages), and that the acute or "neurotic" effects of thyroidectomy are accidental and, like the symptoms of parathyroidectomy, may be accounted for (1) by the youth of the animal operated upon—the "acute" symptoms are always most common in young animals and are usually absent in old animals; (2) the interference with the rich nervous connections of the thyroid during the operation; and (3) the wounding of the thyroids, in consequence of which colloid is spilt and thyroidism is produced by absorption of the juice. Where surgeons meet with this mishap it is common for them to have a more than usually distinct febrile reaction and tetanic symptoms after the operation. In the removal of the internal parathyroids, which are usually incorporated in the deep surface of the thyroid, the thyroid cannot escape severe manipulation or even actual wounding.

'CIMICIFUGA IN TINNITUS AURIUM.

Dr. Albert Robin and Dr. Mendel extol cimicifuga in this complaint, and cite, among other cases, one in which a plug of wax, the obvious cause of the buzzing, was purposely left, while the buzzing disappeared in two days under treatment. Here are their conclusions: (1) Buzzing of the ear may be considered as the reaction of the auditory nerve to direct or reflex irritation; (2) Cimicifuga racemosa possesses an action upon the auricular circulation and upon the reflex irritability of the auditory nerve—the average active dose is thirty drops of the extract a day; (3) buzzing which has existed more than two years appears difficult to influence by cimicifuga.—New York Medical Journal, July 23, 1898.

THE ACTION OF SUPRAARENAL EXTRACT ON THE CIRCULATION.

Velich (Wien. Med. Woch., 1898, No. 26) has confirmed Schäfer and Oliver's discovery that injection of suprarenal extract raises the blood-pressure and stimulates the vagi, and where these have been put out of action or the medulla cut through, causes acceleration of the pulse. The former effect is due to contraction of the small vessels, particularly in the abdominal cavity, the latter to direct stimulation either of the heart muscle or the intracardiac ganglia, together with some influence through the cervical cord. He has also shown that even where the whole cord has been destroyed the injection of large doses of suprarenal extract still causes a noteworthy rise of blood-pressure, which must thus be produced by stimulation either of the vessels themselves or of the peripheral vasomotor mechanism. Continuing his investigations, Velich finds that the medulla is also concerned in the rise of blood-pressure following injection of suprarenal extract, and that intravenous injection still causes this rise in animals which have been deeply poisoned with curare or chloral. These drugs in large quantity practically abolish the functional activity of the spinal cord. In deep curare poisoning the pulse acceleration occurs also when the vagi are intact, showing that their nuclei are poisoned by a large quantity of the drug.

A further series of experiments was performed upon the pulmonary circulation in order to decide whether vasoconstrictor fibers for the pulmonary vessels exist. It was found that the intravenous injection of suprarenal extract leads to a slight rise of pressure in the pulmonary circulation. The principal cause of this rise is that the right heart receives an increased supply of blood from the hyperemic brain through the superior vena cava, while the left heart does not empty itself properly. Hence the existence of a special vasoconstrictor mechanism, central or peripheral, for the pulmonary circulation cannot at present be established. Thus, for example, warm suprarenal extract causes vasoconstriction when applied to most parts of the body in animals or to the human skin, but evokes no pallor when dropped on to the surface of the lungs.—British Medical Journal, Aug. 6, 1898.

QUININE HEMOGLOBININURIA.

Murri (Arch. Ital. de Biologie, tome xxviii, fasc. iii, 1897) reports a case of this affection. A girl aged seventeen contracted tertian ague in July, 1893. In spite of treatment she was not cured in January, 1894, and was still taking quinine. At that time she had an attack of ictero-hemoglobinuric fever directly after taking quinine, and subsequently whenever quinine was taken such
an attack was observed, consisting in rigors, vomiting, followed by smoky urine, and lastly, jaundice. The spleen became larger and firmer, and sometimes the liver enlarged also, with hypochondriac pain. At the beginning of an attack there was simple polyuria; then from being acid the reaction became alkaline; and lastly, peptone, serum albumen, globulin, hemoglobin, and uroblin, hyaline casts, epithelial renal cells, and leucocytes, but no red corpuscles or bile pigment, appeared. After an attack the above all disappeared, the serum albumen and peptone last. An examination of the blood showed there was a diminution of the number of red corpuscles, but the malarial parasite could never be found. In spite of this effect of quinine it had its usual influence in prolonging the interval between the attacks of true malaria.

The author gives reasons for believing that quinine hemoglobinuria occurs only in those whose organs have been altered by malaria, quinine alone being insufficient to produce it: (1) For twenty years he has been trying to produce quinine hemoglobinuria in animals without success. (2) In a healthy man 75 or even 300 grains of quinine produces no hemoglobinuria, while in this girl, after malaria, 1.54 grains did with absolute certainty. (3) No case of quinine hemoglobinuria has been reported which was not complicated by malaria. (4) The proof that one has not to do with an idiosyncrasy in a person with whom malaria is a coincidence is furnished by the fact that quinine intoxication appears in most cases, sometimes after a good many doses have had to be taken—that is, after the malarial poison has had time to act on the organism, but not before. (5) It is not produced by an intolerance gradually set up by repeated doses of quinine, for large and repeated doses are often given in non-malarial diseases, and yet not a single case of quinine hemoglobinuria has been reported in these. (6) This hemoglobinuria is almost unknown in Europe, except in Sicily and Greece, and becomes relatively frequent in extra-European countries where malaria is more virulent. (7) The author's patient had three ictero-hemoglobinuric attacks after the malaria was cured, and without any quinine having been given. This shows that the hemoglobinuric mechanism had become so easily set in motion that its usually specific stimulus (quinine) could be replaced by others, though exactly what these were could not be discovered. It seems as though the biographical change left in the patient by malaria would not be permanent, for some months after the patient had been cured of her malaria and had had no quinine attacks a little over 1½ grains of quinine given experimentally had very little effect, and even 7½ grains, though causing intoxication (fever, albuminuria, peptonuria, and uroblinuria), produced no hemoglobinuria.—British Medical Journal, Aug. 27, 1898.

**HEMORRHOIDS AND THEIR TREATMENT.**

The Medical News of August 6, 1898, contains an article on this topic of no little interest, by Dr. Erdmann. From his standpoint, hemorrhoids are distinctly a surgical affection, although the palliative treatment will receive its share of consideration. The close association of hemorrhoids with the genitals makes the discussion doubly interesting to the specialist and the general practitioner. It is not the object of the writer to enter into a prolonged discussion of the causes, nor is the anatomy to be considered in detail, but he trusts that a short description of the pile-bearing area and a few words relative to the causes of hemorrhoids will not be amiss.

The pile-bearing area is but about two and one-half inches in length, beginning at the anal margin, richly supplied with branches from the sacral plexus, and abundantly furnished with arterial and venous channels. It is interesting at this point to note the descriptions given to the end filaments of the veins. They are variously stated as ending in the so-called derivative circulation to that of small sacculations or dilatations, and it is this latter description that is most frequently accepted. To this accepted venous termination the entire hemorrhoidal theory is ascribed. The arteries supplying the pile-bearing area assume a course parallel to the long axis of the bowel instead of transversely, as in the remainder of the intestinal tract. The mucous membrane in this region is peculiarly arranged, particularly so at the lowermost portion of the area. Here the membrane is thrown into folds or columns, forming sinuses known as the columns and sinuses of Morgagni. These folds and columns, with their intervening pouches, frequently, especially so when inflamed or congested, are taken for piles, and it is in this structure that the quack finds his rich reward. These pouches can be everted in all cases, when the bowel is in a normal state, by placing the hands on the buttocks, the patient
then bearing down, and as he does so traction being made on each buttock with the fingers. They will then be seen as folds of mucous membrane, and resemble small semilunar valves with their concavities upward. A probe can be passed downward behind the membranous-like flap for a distance varying from one-sixth to one-half an inch, and owing to this peculiarity they are frequently but wrongly called fistula.

One who sees many cases of these protrusions is astounded in taking the histories at the percentage of patients who ascribe their disease to attacks of diarrhea, although almost all accepted authors lay great stress on the influence of constipation as the causative factor. It cannot be gainsaid that a relative condition exists between varicose veins and hemorrhoids, as in a great many cases of hemorrhoids other varicosities are found. Naturally, with a predisposition to varicosities in the veins at other parts of the body, a very slight exciting cause is necessary to produce the evil. Some of these causes are obstruction to the venous return, as produced by constipation; intrapelvic tumors; retrodisplacements of the uterus; pelvic exudates; atonic condition of the musculature of the rectum and sigmoid; rigidity or stricture of the anus; expulsive efforts as noted during attacks of diarrhea, and in the expulsive efforts when the outflow from the bladder is for any reason involved, as in cases of stone, stricture of the urethra, enlarged prostate, cystitis, etc. Alcohol, sexual excesses, masturbation, and even unsatisfied sexual desire, are said to be predisposing factors. High living and sedentary habits are also contributing causes. Recently the writer operated in a case which was said to have had its origin in physical exercise. The patient in this case was a prominent amateur athlete, who said that his condition was due to overtraining.

In the general symptomatology the cardinal objective sign is the protrusion of a mass either constant or only seen following the act of defecation. This protrusion varies in size from that of a pea to one that practically surrounds the anal margin, and is from a quarter of an inch to an inch or more in length. Hemorrhage, as a sign, is as likely to accompany irritable ulcers, the so-called fissures, fistule, malignant diseases, and polypi, as it is to accompany hemorrhoids of the bleeding or capillary variety. Subjectively, the patient is apt to complain of pain at the time of or immediately after the act of defecation, discomfort, and a sense of an imperfectly emptied bowel, and of tenesmus, which is frequently due to the sphincter grasping the protruding bowel mass. Pain is frequently present in the lumbar region, which may even extend to the thighs and legs. In addition to the symptoms directly referable to the anal region, there is frequently a chain of nervous symptoms of which mental depression, probably due to the fear of the trouble becoming malignant, irritability, fear of some impending disaster, and sexual impairment predominate.

Hemorrhoids, as far as the general practitioner is concerned, may be divided into two great classes, the external and internal. The external ones are those which arise from the tissues outside the external sphincter, while the internal variety consists of those which arise from the lower portion of the rectum, and are seen only when protruded after a movement of the bowels, or protruded as a result of some physical effort, or can be seen upon instrumentation with the speculum or the Kelly proctoscope. The external are subdivided into three varieties—the thrombotic, the cutaneous, and the venous. The latter variety is liable to become edematous, and is then called by some the edematous pile. The thrombotic variety is usually found in the mucocutaneous margin surrounding the anus. They are due, as a rule, to rupture of one of the veins about the anus, occurring as the result of straining during the act of defecation. The pile is hard, very painful, sensitive to the touch, bluish in appearance, and contains clotted blood. The second variety, the cutaneous, is a natural sequence of the thrombotic variety—i.e., the clot is absorbed or organized so that its original site is filled with fibrous tissue. In this type there are, as a rule, no further subjective symptoms than an incessant pruritus, well marked at night and after physical exercise. The third variety of the external—i.e., the venous—borders very closely in its anatomic appearances upon the type of internal hemorrhoids known as the columnar, pedunculated, or venous. In this variety of external piles there is an involvement of the mucous membrane and skin of the anus; the veins are dilated, and the mass may consist of but a single set of vessels or be of such dimensions as to almost completely surround the anus. The symptoms of this variety, barring inflammation and ulceration, are those of a protrusion non- or partially reducible, not painful and not bleeding, except when inflamed.
or ulcerated. The internal class may be divided into two varieties—the capillary, or bleeding, and the columnar, venous, or pedunculated. The capillary pile is never seen externally except in cases of relaxation of the sphincter or of dilatation of this muscle. These piles resemble masses of deeply congested mucous membrane, and bleed upon contact of the finger or fecal mass; in fact, they resemble masses of healthy granulation tissue. They are seen upon the use of the speculum and proctoscope, and ordinarily present no evidences to digital examination. Blood is seen after each movement, varying in quantity from a few drops to several drachms. In addition to the local evidences, all of the manifestations of anemia are frequently seen, while the patient presents a subjective chain of symptoms which are entirely of anemic origin. This variety will eventually result in the columnar type. The second, or columnar variety, usually known by the names of venous or pedunculated, are made up of a mass of dilated veins and one or more arterial twigs. They protrude upon straining or defecation, and are readily reducible, except in case of neglect, when they are liable to become strangulated, edematous, or undergo ulceration and slough. Should any of these changes occur, it then assumes all the evidences of an inflamed pile. These pedunculated piles can be felt upon digital examination, and seen readily with the use of the speculum or proctoscope.

In examining the patient externally, the Sims position is the best, provided that the buttocks are well separated and the patient strains as though about to have a movement from the bowel; when this is done almost an inch more of the mucous membrane will be protruded than when in the stooping position. For digital examination, either the lateral or dorsal position of the patient is satisfactory. The finger should be protected with a finger-cot, thoroughly anointed with some bland lubricant. Gentle pressure is then made upon the sphincter until its rigidity is overcome. These finger-cots are so thin that the tactile sensation of the finger is not impaired to any extent, while, in addition, they protect the physician from infection and keep the examining finger clean. For speculum or proctoscopic examination the bowel should be thoroughly clean, and in all sensitive cases anesthesia should be produced. Anesthesia permits of a complete examination being made with a view to locating fistula and ulcers, which are frequently present in these cases.

**Intestinal Obstruction.**

Professor Kocher, of Bern, read a paper on intestinal obstruction. It is still only too common, he remarked, to find cases treated by drugs before the surgeon is consulted. He had had seventy-seven cases of intestinal obstruction (excluding cases of disease of the rectum and external hernia); of these, twenty-six were due to malignant diseases of the bowel, and he resected the intestine in twenty-four of these cases with only four deaths. In nineteen cases tuberculous masses had produced stricture of the bowel; in eighteen of these he operated, and only one patient died. If the moribund cases and those where no operation was done were excluded there remained thirty-eight cases in which an operation was performed, and in these the mortality was only eighteen per cent. It was, however, curious that in the slighter cases, where the ileus might be said to be symptomatic, the mortality was much higher; of seven cases of volvulus there were five deaths. In fact, in the simpler cases the death-rate was fifty-nine per cent. The logical deduction from these statistics is that the great mortality is not due to the operation. The cause of death in most cases was septic absorption from ulcers occurring in the bowel above the obstruction; these ulcers were usually attributed to pressure from feces, but they occurred even when the feces were liquid; they were really due to overdistention, which led to impairment of the epithelium. It was necessary to relieve the distention as soon as possible, and this might be done by a small incision, a radical cure being postponed to a later date. Finally, he urged that surgeons should be called in to see a case of obstruction before any drug is given, and it was very advisable for the surgeon to have the benefit of the physician's opinion when making the diagnosis. — *The Lancet*, July 30, 1898.

**Common Errors of General Practitioners in Dealing with Cases of Pulmonary Tuberculosis.**

F. I. Knight, so well known as an authority on pulmonary disorders, tells us of the errors of physicians concerning pulmonary tuberculosis in the *Boston Medical and Surgical Journal* of November 17, 1898. These errors are well known to the profession and encountered by many of them daily, and he thinks they may be diminished by briefly calling attention to them.
The first error to which the author calls attention is the failure to make an early diagnosis. An early diagnosis is not usually difficult since the discovery of the tubercle bacillus. Failure to make it, however, may be very serious, as it is especially true of this disease that the earlier its presence is discovered the more amenable it is to treatment; whereas, if there is delay till the disease is self-evident and perhaps secondary infections have taken place, there is not much chance of restoring the patient to health. The most striking results of treatment of pulmonary tuberculosis in the great open health resorts and also in sanitariums are in patients who present all the outward aspects of health from the start, who have never appeared as invalids.

Why is it that there is so often a failure to make the diagnosis early in those cases most promising of cure if taken in hand promptly, namely, those with morning cough and expectoration, but no fever or other general symptoms? The reason is that the patient naturally makes light of it, and perhaps contents himself with asking the doctor on the street for a prescription for a little cough, and this may be repeated several times without any suggestion of examination on the part of the physician, or until the patient looks and feels sick.

Another reason is that the physician may be the personal friend as well as medical adviser of the patient and shrinks from a knowledge of the results of a physical examination. This is also sometimes true in cases of a physician and a member of his own family.

The patient naturally considers a slight dry cough as due to some throat irritation, and a little hemoptysis as coming from the same region; but he should not be encouraged in this idea, as is too often the case, by the physician. Any cough should necessitate frequent examination of the chest, until the soundness of the lungs is proven by long acquaintance. Hemoptysis very rarely comes from any lesion of the throat, but usually from the bronchi. Another mistake is neglect to pay proper attention to fever, the physician very likely coinciding again with the patient that he has a “touch of malaria.” Time and again has the writer seen patients with a dry cough, chills and fever—not at all of malarial type, however—allowed to go on for weeks and months taking quinine, and no physical examination suggested.

A second error is the failure to admit the gravity of the situation the moment it is discovered, and to put the patient at once in the best possible condition for recovery. Niemeyer used to say that the danger of a consumptive patient was “that he become tuberculous.” In the light of modern pathology the writer states that he should say that the danger of a tuberculous patient is “that he become consumptive”—that is, subject to secondary infections.

Unfortunately, too many physicians wait till the patient is consumptive, and then perhaps recommend expensive treatment, which is almost surely useless.

It is better, as a rule, that the patient also should be fully informed of the gravity of the situation, as in this way only will he give thorough cooperation in the effort for his recovery. Of course, he should be fully impressed with the hope of recovery if the proper course is pursued.

A third error is, while temporizing, recommending treatment not only useless, but positively injurious. Giving medicines which take away the appetite and interfere otherwise with digestion does a great deal of mischief. Cough syrups, cod-liver oil, and creosote do a large share in hastening the decline of patients. If any sedative is required it should be given in as simple a form as possible, and without syrup. The author does not mean to say that cod-liver oil never does good, for there are patients who can take and assimilate it with ease, and greatly to their benefit, but it is cruel to prescribe it in a routine way without selecting cases and watching effects. Who has not many times seen patients with thickly coated tongues swallowing large doses of oil faithfully three times a day, eructating it all the time, and capable of assimilating neither that nor any other food? Neither will be deny that creosote does good in some cases in modifying the bronchial secretion and improving digestion, but he believes that large doses as a rule take away the appetite and do more harm than good. It, like cod-liver oil, should be administered tentatively.

Another unfortunate mistake is often made in giving a general unrestricted order to “drink whiskey” as a preventive of consumption. The injudicious use of alcoholic stimulants, by depressing the vital forces, not only makes the patient irritable and dissatisfied with himself and everybody else, but very seriously interferes with his recovery.

Many patients also are seriously injured by being told to exercise when they should
be kept quiet. This pertains especially to patients in a febrile condition.

A grievous error is often committed in the matter of sending patients away from home. Sometimes those are sent away who have only a few weeks or months to live. Such patients in almost every case would naturally be better off at home. Others are advised to change climate who cannot possibly afford to remain away from home long enough to do any good. They go away, live in miserable quarters, on poor food, and having spent all their money, in a short time are obliged to return. They naturally would have spent their little money to much better advantage at home.

Insufficient care is exercised in advising patients who are able and fit to make a change as to the selection of a climate. Too often the advice is simply to "go south" or "go west." In such cases the patient often flits about from one climatic condition to another, without staying long enough to fully experience the modifying effect of any one, perhaps till the chance for beneficial action is past.

The last error, a very grave one also, to which the author calls attention is allowing the patient to go without sufficient medical supervision. This disease, like any formidable enemy, requires constant watchfulness—to help gains promptly, and as promptly to stay relapses. The general practitioner himself is apt to fail in this because his attention is absorbed in critical acute cases; but he also fails to place his patients in proper medical care when he sends them away, whereas the presence of a physician skilled in treating such cases should often determine the selection of a residence for the patient.

These are a few of the more serious of the errors in dealing with cases of pulmonary tuberculosis, by means of which hundreds of lives are sacrificed which might have been saved. Therefore it becomes us to reiterate and reiterate our warnings as long as the dangers continue to exist.

THE TREATMENT OF CHOREA.

An article with this title is contributed to Treatment of November 10, 1898, by Wynter. He thinks that the first matter of importance in the cure of chorea consists in keeping the child in bed, necessitated by the tendency to endocarditis, and emphasized by its beneficial effect in shortening the disease or bringing about a speedy cure in cases where it has existed without material benefit from drugs for weeks and months while the child remained up and about.

The efficiency of treatment by arsenic is often marred by insufficiency of dose. It is common practice in the case of children, who make the bulk of the patients with chorea, to prescribe two or three drops of Fowler's solution. This may answer in a few mild cases, but in the majority it is insufficient, and the dose must be increased to ten or even fifteen drops in the course of ten days or a fortnight if the symptoms do not decline. A good example of this was afforded by a child of five, who was admitted to the Middlesex Hospital with extensive movements, and in whom a dose of three minims given for some weeks produced little or no effect; but on doubling the dose for three days, and then quadrupling it, the movements rapidly subsided. Tolerance is readily secured if the drug is not given in too large a dose at first or the dose increased too rapidly, the medicine always being given, with sufficient dilution, immediately after food.

That the exhibition of arsenic may in some cases be carried too far and produce serious neuritis is exemplified in cases exhibited at the Clinical Society during 1898 by Dr. Batten, in which fifteen minims of Fowler's solution had been given three times a day. As in the case of antipyrin rash, this accident is more likely to occur when the patient is not kept in bed, so that the intensity and duration of medication are increased to combat the unfavorable influence of activity and excitement. This furnishes an additional reason for keeping the patients in bed under close observation during treatment by powerful drugs.

In all the cases a liberal diet is required without stimulants, the subjects of chorea being usually of a thin and nervous type, and the disease itself exhausting and commonly associated with anemia and debility.

The principal complications are endocarditis or pericarditis, which in the acute stage are best treated with salicylates, as in rheumatism. The indications are chiefly a hurried, weak pulse, with palpitation, some precordial discomfort, and perhaps a soft blowing murmur or friction sound. They are so slight, and may be so ill-developed, that in a restless child it is easy to overlook them. Only in the latter stage, of contraction deformity of the valves, do the rough murmurs with evidence of cardiac enlargement and back-working show themselves.
In a few cases in which the actual movements are so violent and continuous as to bring about contusion and abrasion of skin, with exhaustion, wasting, and loss of sleep, direct sedatives are required. Chloral and the bromides are then generally serviceable, the dose being daily increased from ten or twenty grains until either the symptom is subdued or physiological effects of the drugs produced. If this treatment fails, recourse must be had to subcutaneous injections of morphine or even the inhalation of chloroform.

When the active phase of the disease declines the patient still needs care and treatment on account of the remaining anemia and debility, the mental condition of hebetude and intractability, and the tendency to recurrence of the malady, apart from the more serious heart complications which may have resulted.

The best tonics are the milder preparations of iron, either the wine or citrate, with liquor arsenicalis in comparatively small doses (three to five minims), or cod-liver oil; absence from competition with others, either in school or on the playground, for some months, which are best spent at the seaside or in the country, where quiet amusement can be obtained without books or boisterous companions. In protracted cases and during convalescence great benefit may be derived from massage, passive exercises, or such diversion as may be obtained in the use of a skipping-rope or hoop. For the most part it is best to avoid books and such toys as appeal to the imagination and provoke spontaneous activity of the brain.

ANTIDIPHTHERITIC SERUM IN OZENA.

Holger Mygind, of Copenhagen (Journal of Laryngology, Rhinology, and Otology, August, 1895), has treated ten cases of ozena with subcutaneous injections of antiphteritic serum. Of these, seven were young soldiers, aged nineteen to twenty-two; while three were girls, aged respectively ten, twelve, and fourteen, all three being sisters, and daughters of a non-commissioned officer. He took great care to select only such cases for treatment as were pronounced and true cases of genuine ozena, and in all there were present typical fetor, discharge of crusts, and atrophy of some part of the osseous walls of the nasal cavity; besides, in all cases the mucous membrane of the nose was of the character generally described as atrophic—

that is, it was pale, shrunk, and dry. He first commenced injecting subcutaneously twenty cubic centimeters of the antiphteritic serum prepared in the bacteriological laboratory of the Copenhagen University gratuitously for the Danish medical profession. This serum has a strength of about one hundred antitoxin units in each cubic centimeter. The dose was repeated—as is done in cases of diphtheria—a few days later. This dose was soon found to be too strong, or could not at least be repeated so soon, the patients getting severe symptoms of serum infection. By degrees he found ten cubic centimeters to be a proper dose for adults and five cubic centimeters for small children, increasing the dose now and then to fifteen cubic centimeters in adults. He also found it best to wait to repeat the dose until eight to twelve days had elapsed after the previous injection, to prevent cumulative effect.

According to the numerous experiments the author has made there can be no doubt that it is a fact that subcutaneous injection of antiphteritic serum in cases of genuine ozena has an immediate and very marked effect upon the mucous membrane of the nose. This action generally appears toward the end of the first twenty-four hours after the injection, the patient discharging the crusts with more ease; besides, the crusts are mixed with mucous or mucopurulent secretion. During the following days the mucous membrane of the nose loses its dry and pale appearance, becoming moist and assuming a natural vivid-red color, and also swelling considerably. The color and the swelling are very different from the color and swelling of the mucous membrane as seen, for instance, in cases of using Gottstein's tampons or copious syringing, having as a rule not the slightest appearance of irritation. Besides, the crusts are seen to be surrounded with mucous secretion, which also appears on the surface of the mucous membrane where there are no crusts. After this period of reaction a period of counter-reaction generally is seen, the pituitary membrane beginning to assume its red character; but after a second or third injection—a greater number of injections might perhaps be necessary now and then—Mygind has, in all cases observed by him, seen a lasting improvement. This improvement has in a few of his cases been only small, though distinct; in most cases it has been very considerable, the patients having lost the fetor, and either never discharging any crusts or only discharging small ones
now and then. In one case the result approached very near to recovery.

Mygind concludes by expressing the opinion that the injection of antitoxin serum is the most effective remedy for ozena yet known. He has made experiments to determine what it is in the serum that produces the effect. They are not yet complete, but he has satisfied himself that the presence of the toxins is of no importance, but that it is the serum alone which acts. He adds that he has obtained results apparently as good as those here reported by injections of normal horse serum in ozena.—*British Medical Journal*, Oct. 22, 1898.

CARBOLIC ACID POISONING.

Levin (*Deutsche Medicinische Wochenschrift*, April 21, 1898) appendes some remarks upon a suspected case. The severity of the poisoning may be due: (1) to the place from which the poison gains access into the blood; (2) to the quantity taken; and (3) to the concentration. Many cases of fatal poisoning have been recorded where a non-lethal dose has been injected into the rectum for the purposes of treatment. Death has been known to occur after a dose of six grains taken by the mouth, and recovery has ensued after doses of thirty or thirty-five grains; in the latter case the carbolic acid was dissolved in alcohol, which would favor its absorption into the blood. Even 120 grains of raw carbolic acid has been taken, and recovery ensued. One grain of carbolic acid, the amount found in the suspected case, could not produce death. The author found that when animals were poisoned with concentrated or weak solutions of carbolic acid, and this was allowed to remain in the stomach after death, appreciable quantities could pass out through the stomach walls into the abdominal cavity. Death may sometimes be produced without the poison entering the blood in a so-called reflex fashion. As regards the action of carbolic acid on the mucous membranes, a one-per-cent solution produces no change, and a two-per-cent a slight color change, to be seen only on careful examination. A four- or five-per-cent solution produces a white discoloration, which disappears in the living subject in three to four hours. Fluid ninety per cent, or the crystalline substance, calls forth a white slough upon every tissue of the body, whether applied pure or in water. The symptoms produced by carbolic acid vary: (1) If a concentrated solution (sixty to ninety per cent) is drunk, the patient may die rapidly with or without previous vomiting, or he may become comatose, with stertorous breathing, slow pulse, vomiting, etc., from which he may die or recover; (2) if weak solutions (one to three per cent) are taken, there may be prostration, unconsciousness, spasm, vomiting, etc. When weak solutions are taken into the stomach the symptoms develop slowly, giving time for treatment.—*British Medical Journal*, Oct. 22, 1898.

EXERCISE AND OVEREXERCISE.

Dr. Lauder Brunton opened the session of the York Medical Society recently by an address on exercise and overexercise, in which he said, as was to be expected, a great many wise things with which every physician will agree. He said, for instance, that exercise which put into action every muscle of the body, but did not put any one into action for too great a length of time at once, or in too violent a manner, was exceedingly beneficial, but in applying this excellent principle he had the temerity to compare unfavorably with lawn tennis the three most popular physical recreations of the day—cricket, golf, and cycling. Moreover, he classed together croquet, cricket, and golf—rather a curious collection—on the ground that in playing them there was not the same general movement of the whole body that was necessary in lawn tennis or polo.

As to croquet all will probably be ready to agree, but as to cricket and golf it is not likely that their devotees will be disposed to accept Dr. Brunton’s rather sweeping assertion. What muscles of the body are brought into play in lawn tennis which are not brought into play by, say, a fast bowler, we should be rather curious to know; and as to golf, the distribution of the stiffness after a day’s play in a man out of condition and practice leads at least to the suspicion that very few muscles in the body have not been called into action. As to cycling, Dr. Lauder Brunton said that it tended to narrow the chest and to cause more or less a permanent stoop. He added that, as it had become so very general an amusement, its physical exercises must be very carefully watched. Like most of us, Dr. Brunton has been struck by the fact that the girl of the period tends to be divinely tall, and he seems disposed to put this down to the great popularity of lawn
tennis a few years ago. It is certainly a pity that this very excellent game appears to be going out of fashion owing to the great popularity of cycling, which we should be disposed to agree with Dr. Brunton is not an exercise so well calculated to produce an all-round development of the muscular system.

Although Dr. Brunton spoke in faint praise of cricket and golf, he admitted that they shared with tennis one essential feature of a good game—intermittent action of so many groups of muscles. Passing on to speak of overexercise, he observed that what was sufficient exercise for the muscles might be over-exercise for the heart, so that schoolboys ran a risk of injury if their athletic power were judged from their apparent size and strength and not according to the strength of the heart.

Dr. Brunton then pointed out that a continuous strain upon one set of muscles was not only painful and exhausting but injurious, and illustrated this point very happily by referring to the fatigue experienced by men and women employed in shops who were compelled by custom to stand for many hours a day. He showed a rest by means of which a shopwoman could sit down and take the weight of the body off the legs, whilst movements behind the counter were hardly interfered with. The cause of the quickened breathing associated with muscular exertion was really the poisonous products formed by muscular action, and the shortness of breath was due to heart disturbance. Thus, in the case of growing boys, football or paper-chases might lead to distinct heart strain.

Another factor which Dr. Brunton said must be regarded in exercises for boys and young men was that mental fatigue caused bodily exhaustion. If boys were pushed both at lessons and at exercises they were much more likely to break down than if they were pushed at one or the other alone. In adolescence the heart, like other muscles, though it was more easily strained, recovered more readily, and with moderate care would recover completely.

In conclusion, Dr. Brunton dwelt on the important point that, while in middle life the heart was less liable to strain, yet as age advanced, and especially if the arteries became atheromatous, the heart was not only more easily affected by strain, but had less power of recovery—a fact which has its obvious bearing on the kind and amount of exercise which should be taken as age advances.—British Medical Journal, Oct. 22, 1898.

ORGANOTHERAPY IN DIABETES.

With the discovery of the value of the thyroid treatment in cases of suppression of the functional activity of the thyroid gland, a new hope arose that some other grave and hitherto intractable diseases might be favorably influenced by treatment based on similar lines. Diabetes was one of the diseases to which early attention was given in this regard. Experiment has distinctly proved that extirpation of the pancreas in certain animals will surely produce diabetes, and morbid anatomy has equally demonstrated that in at least one class of cases of human diabetes a total disorganization of the pancreas has sometimes been found; thus it appears that diabetes might be due to the suppression of some function of this organ, and this apart from the mere secretion of pancreatic juice. It was therefore hoped that pancreatic feeding might supply the deficiency in the same way as thyroid feeding had so distinctly supplemented the functions of the thyroid body.

These expectations have not, however, been realized, and with few exceptions the treatment of diabetes proved to be of the pancreatic variety; but feeding with pancreas has ended in disappointment.

Dr. Ferdinand Blumenthal has recently endeavored to throw light on the causes of the failure of this treatment of diabetes, and to indicate the lines of investigation to be pursued in the future. The gist of the whole question obviously lies in the discovery of the active principle of the pancreas, the absence of which is believed to lead to the development of the pancreatic form of diabetes. Experiment renders it probable that this active principle is a glycolytic ferment; distinct, as the researches of Blumenthal himself as well as others show, from the oxidative ferment. On this supposition a rational treatment of diabetes would consist in supplying this ferment in cases in which it was absent through disease of the pancreas. This ferment may be destroyed by various secretions, such as those of the stomach, or it may be insufficiently absorbed from the bowel. In such cases the use of pancreatic gland tissue containing active glycolytic ferment would be rendered nugatory. Or, again, glycerin or saline solution may fail to extract the glycolytic ferment from the pancreas, with the consequence that sometimes an inefficient preparation may have been used in treating diabetes by the subcutaneous method.

It is not assumed that this glycolytic ferment is exclusively manufactured in the pan-
creas, and hence the treatment would apply to cases of diabetes not necessarily of pancreatic origin. Professor v. Leyden saw a case of diabetes markedly improved by the use of the juice expressed out of the pancreas, and Blumenthal, availing himself of Leyden’s suggestion, has been able to prepare the glycolytic ferment in considerable quantities. Thus under a pressure of 70 to 90 atmospheres he was able to obtain from 500 grammes of pancreas 100 to 250 cubic centimeters of fluid rich in ferment. This fluid can be kept under ice for more than ten weeks without the addition of any antiseptic. The sugar solutions used for testing this ferment must, of course, be sterile. Blumenthal mentions that alcohol does not destroy the ferment if left in contact with it for only a few hours, and that hence the ferment may be obtained in a dry form. A difficulty, however, lies in the administration of the glycolytic ferment, since it is extremely poisonous when given subcutaneously to rabbits, and dilution does not overcome these deleterious properties. The author says that the task of finding an efficient and harmless glycolytic ferment prepared either from the substance of organs or from plants must remain a problem of the future.

These researches will be watched with interest, but it must not be forgotten that Minkowski failed to benefit depancreatized dogs by the hypodermic injection of pancreatic emulsion, and it has yet to be shown that Blumenthal’s juice, although active in vitro, possesses therapeutic properties even in animals. — British Medical Journal, Oct. 22, 1898.

CORNEAL ULCERS AND THEIR TREATMENT.

The London Lancet of October 22, 1898, has an article by Percy Dunn in which he refers when speaking of this condition to two drugs—namely, chinosol and eserine—and about each of these he adds some details. With regard to chinosol, concerning the advantages of which the writer has been repeatedly asked, he believes it to be the best antiseptic agent which is now in the market, and the longer he uses it the more he prefers it and the closer does it seem to him to fulfill the requirements of an ideal preparation of the kind. There are certain reasons for doubting whether in ophthalmic surgery the principles of antisepticism are followed in the present day to the extent which their importance demands, and it is probable that the want of precision in this regard is partly due to the fact that among the multiplicity of antiseptic agents there is none which has actually found general favor with ophthalmic surgeons. The perchloride of mercury, carbolic acid, boric acid, each has its drawbacks. Each is undoubtedly useful in its way, but neither the one nor the other has ever excited sufficient enthusiasm to cause thorough antiseptic principles to prevail in the domain of ophthalmology. The importance of this matter he believes to be such that he holds sympathetic ophthalmia would be an impossible complication in eye surgery were a wound of the ciliary region to be treated from the first with every antiseptic precaution. In fulfilment of this belief he has treated within the past year several severe wounds in the dangerous zone, and in each case the eye made an excellent recovery.

The results the author has attributed to the systematic antisepticism practised by means of chinosol. The chemical name of this drug is potassium oxyquinoline sulphonate, and one of its chief advantages is the potency of its germicidal action—a fact which has been incontestably proved by bacteriological investigation. In addition, it is freely soluble in water, and thus is handy for use. Moreover, it is non-caustic, does not injure the skin of the hands, does not coagulate albumen, and is non-hygroscopic. Again, it is one of the most economical preparations in the market, for owing to its potency only weak solutions of the drug are necessary. Mixed with 1 in 20 of boric acid it forms an admirable antiseptic ointment. It might, perhaps, seem that in saying all this the writer is praising chinosol inordinately. The fact, however, is that a lengthened experience has taught him that it is an excellent preparation, possessing advantages which in time must command it to every operating surgeon.

With respect to eserine, there is some unanimity of opinion among the authors of modern text-books on ophthalmic surgery that the drug should be avoided in the treatment of corneal ulcers. The author’s experience, as will have been gathered, does not accord with that view. On the other hand, he believes that the feeling which prevails against eserine in this connection has arisen in consequence of misconception regarding its use. The great point to remember is to use it in a weak solution. The evil repute of the drug has been mainly gained by employing solutions of greater strength than
were necessary. Formerly eserine drops of
the strength of four grains to an ounce of
water used frequently to be prescribed, and
then troublesome symptoms were nearly
always induced. But it is seldom, if ever,
necessary to resort to a higher strength than
half a grain to an ounce solution, and for
continuous instillation in cases of chronic
glaucoma even a less strength than this may
be satisfactorily employed.

Experience has fully demonstrated that
there are certain forms of ulceration of the
cornea which atropine fails to benefit, but
which, on the other hand, readily yield to
eserine. To define what these particular
forms are is a question which has been re-
peatedly asked in the writer's out-patient
room, and the answer may here be given as
follows: All sloughing, infective, and vas-
cular ulcers are best treated with eserine, as
well as, of course, those situated at the cor-
neal margin at which perforation is threaten-
ing. This may be regarded as a broad rule
for guidance, but there remain other cases
concerning which no rule can be expressed
in words. The writer has in mind those
cases of simple ulcer in which atropine has
been used and apparently failed. In many
such he has found eserine to act like a charm,
the injection of the globe quickly clearing up
in consequence and the ulcer rapidly be-
ginning to show improvement. A typical
case may here be mentioned. A short time
ago a man wearing a shade was led into his
out-patient room by his wife. The history
was that he had been under treatment at an
ophthalmic hospital for five weeks. There was
a superficial central ulcer of each cornea with
photophobia and some injection of the globes.
The pupils were widely dilated from atropine.
This seemed to be a case in which eserine
was clearly indicated. Accordingly eserine
drops (one-half grain to an ounce of water)
were ordered to be instilled twice a day. At
the end of the week, when the patient again
presented himself, the improvement was very
manifest. Two days after using the drops
the patient discarded the shade and the pho-
tophobia had gone as well as the injection of
the globes. Before the end of another week
he had returned to his work.

Undoubtedly in cases where photophobia
is troublesome eserine is of service by con-
tracting the pupil and cutting off light to the
eye, while atropine increases the trouble by
dilating the pupil, thus placing the patient
with his damaged cornea in a helpless con-
tion in the presence of light beyond a low
degree. It is quite possible that the utility
of eserine in the treatment of corneal ulcers
is partly due to the fact that the drug reduces
the tension of the globe. This is only a
reasonable assumption when we recollect that
atropine tends to raise the tension and that
an eye in which increased tension has oc-
curred is not one in which healthy nutrition
is likely to be present. By lowering the
tension, then, in these cases just the differ-
ence may be made in securing the establish-
ment of those nutritional changes necessary
for the complete repair of the ulcer.

RESTORATION OF SEVERED PARTS.

The possibility of restoring severed parts,
even under unfavorable circumstances, is not
so generally appreciated as it should be, and
attempts which might be successful are not
made. Lately we published three cases in
which the severed external ear was success-
fully replaced. In one (Dr. Brown's) the
circumstances were anything but encourag-
ing. The ear had been bitten off by a horse
and was found lying in a stable yard. Neither
surgical instruments nor antiseptics were
available; a common needle and thread had
to be used. In the other two cases (Dr. Pur-
cell's) the surgeon adopted the ingenious
plan of keeping the ear warm and endea-
voring to restore the circulation by hot salt
bags. We do not know of any other instances
in which this has been done in the attempt to
restore severed parts. To what extent it is
useful it is difficult to say; at any rate, it is
rational.

Several cases of union of severed finger-
tips are recorded. In the Johns Hopkins
Hospital Bulletin, October-November, 1892,
Dr. Finney has published a case of success-
ful suture of severed finger-tips after seven
hours. The middle finger was cut off just
below the last joint through the phalanx, the
ring finger at the root of the nail. The raw
surfaces were freshened and the tips were at-
tached each by four sutures. Dr. Finney
used antiseptic dressings, but not solutions,
because bichloride of mercury and carbolic
acid produce a thin layer of coagulation nec-
rosis. The wounds united by first intention.

In a recent number of the New York
Medical Journal appears an account of the
following case, published in the Louisville Med-
ical Monthly by Dr. John Cook Laurens: A
colored man in using a heavy axe cut through
his shoe and severed the metatarsal bone of the
first toe through the head, completely disar-
taculating the toe, and also cut off the second toe in front of the metatarsal joint. He was seen four hours afterwards. The shoe and sock were cut away and the second toe was found separated, whilst the first was hanging by a mere string of skin, every muscle and vessel being cut. They were united by interrupted sutures which included the tendons. A dressing of iodoform and boric acid, equal parts, was used and a splint was applied. The iodoform had to be discontinued because it proved irritating. Union by first intention occurred over more than half the wound, and there was but little pus where granulation took place. On the third day sensibility was present in both toes, and in a week the patient could move them a little. Finally they were strong, movable, and sensible, and except for a little tenderness the foot was as good as ever.—The Lancet, Oct. 22, 1898.

THE STERILIZATION OF CATGUT BY DRY HEAT.

In the London Lancet of October 22, 1898, Dauber tells us that the following is the method of sterilizing catgut adopted by Professor Tscherning, of Copenhagen, who recently very kindly showed the writer the details observed by himself in its preparation at the Kommune Hospital in that city. The ordinary commercial catgut as it comes from the manufacturer is placed on trays in the sterilizer between sheets of cellulose paper. It is then heated for six hours consecutively, for the first hour at a temperature of 60° C., for the second and third hours at 100° C., and for the fourth, fifth, and sixth at 140° C. It is then removed, wrapped up, and closely sealed in an envelope of cellulose paper, which is again placed in another envelope of slightly larger size and similarly closed. The catgut now encased within two firmly sealed envelopes is a second time placed in the sterilizer and subjected for another two hours to a temperature of 140° C. The envelopes are placed in racks in the sterilizer, and contain various sizes of catgut labeled on the outside, some of a size for ligaturing the pedicle in ovariotomy, others for fine buried sutures or other purposes where absorption is desired within a short period. These envelopes can be taken from the sterilizer and placed in the pocket or bag of the operator, and need not be opened until the time of operation. Thus they are very handy and portable.

It is to be remembered that catgut liga-
tures prepared by any of the wet methods, if kept in spirit for any length of time, become hard and need more time for absorption. If, on the other hand, they are kept in an antiseptic aqueous solution they tend to become soft and lax, whereas if kept in any preparation of glycerin they are somewhat difficult to manipulate owing to their extreme slipperiness. The dry catgut is without these disadvantages. The method of raising the temperature by slow degrees prevents the catgut becoming brittle—the grease and oil in the gut being driven off gradually at the lower temperatures.

FLUORIDE OF AMMONIUM.

M. BAUDOIN (Gazette Hebdomadaire de Médecine et de Chirurgie, Oct. 2, 1898), in his thesis to the Faculty of Paris, relates the results obtained at the Pitie by Dr. Robin with fluoride of ammonium in the treatment of abnormal fermentations of the stomach. Fluoride of ammonium, he says, acts upon lactic, butyric, and acetic fermentations, not only by destroying the ferments, but by modifying favorably the influence of the gastric juice on the digestion of albuminoids and the refuse. Its bactericidal action is not simply transient, but appears definite, as his observations show. Fluoride of ammonium has no noxious action on the chemical fer-
ments of the stomach. It is perfectly toler-
ated and has no toxic action on the organ-
ism.—New York Medical Journal, Nov. 12, 1898.

THE INTRACEREBRAL INJECTION OF TETANUS ANTITOXIN.

The daring procedure first successfully practiced by Quenu and Chauffard, as noted in the Journal of July 14, has been performed for the first time in this country, and the eighth on record, by Dr. Rambaud, of the New York Pasteur Institute, in the case of a patient in Passaic, N. J., who developed tetanus after a lacerated wound of the calf of the leg due to falling through a skylight. A large portion of the calf of one leg was torn completely away. "Antitoxic serum was injected hypodermically but without effect. As a final effort it was decided to resort to the heroic measure of trephining the skull on both sides and injecting the antitoxin directly into the anterior lobes of the brain tissue. This was accordingly done, with the result that almost immediately there was a relaxation of the muscles of the jaw.
Since then improvement has been steady and constant." Dr. Rambaud was present at the first successful operation performed by Quenu and Chauffard, in which Roux injected the antitoxin. The period of incubation of the disease is not stated. It is to be hoped that a fuller report of the case, which is one of great interest and importance, will be forthcoming.

Du Hamel (La Médecine Moderne, Aug. 10, 1898) also reports a case of tetanus occurring in a boy aged fifteen, produced by a pistol-shot wound between the thumb and index-finger. Later symptoms of tetanus developed and he was taken to the Pasteur Institute, where, in addition to hypodermic injections of antitetic serum, three cubic centimeters of a similar fluid was injected in each side of the brain near the fissure of Rolando. At the time the injections were made the patient was in a condition of strong opisthotonos. The contractions gradually diminished, though they did not entirely disappear for some days. In three weeks he was out of the house.—Boston Medical and Surgical Journal, Oct. 27, 1898.

THE TREATMENT OF ANEURISM BY SUBCUTANEOUS INJECTIONS OF GELATIN.

At the meeting of the Paris Academy of Medicine held on November 8, 1898, M. Lancereaux referred to some experiments which he had made upon animals, which showed that in a very short space of time after the injection of gelatin blood drawn from the general circulation would coagulate in a few minutes. In man after an injection he had seen coagulation occur only in the aneurismatic sac. The operative technique of the injection is as follows:

White gelatin in a quantity of from four to five grammes is dissolved in a seven-percent solution of sodium chloride in measure 1000 to 2000 cubic centimeters. The solution is placed in a flask, which is sealed and then sterilized with its contents at a temperature of 120°C. For the injection a flask of the capacity of 500 cubic centimeters is got ready, fitted with a cork and two tubes like a wash-bottle. The long tube is connected with a sterilized needle and the short tube with an india-rubber air-ball. The gelatin is liquefied in a water-bath at a temperature of 35°C and poured into the flask, which is also kept in a water-bath. The injection is made slowly into the subcutaneous tissues and should take fifteen minutes. Thus performed it is not painful and no reaction follows. It should be repeated every six or eight days until the sac is obliterated.

M. Lancereaux said this method, if carried out with care, gave excellent results in the most desperate cases.—Lancet, Nov. 19, 1898.

CLINICAL OBSERVATIONS IN REGARD TO GENERAL ANESTHESIA BY THE SCHLEICH MIXTURES.

The Medical News of November 12, 1898, contains an article by GARRIGUES on this subject. The outcome of the author's investigation is that the Schleich mixtures are easily taken; that they may be used in all cases in which general anesthesia is not contraindicated; that anesthesia can be induced in a short time and kept up with small amounts of the fluid; that there is little accumulation of mucus, little vomiting, hardly any cyanosis; that there is no bad effect on the kidneys; that the heart is not much influenced by it, although somewhat weakened; but that there is some danger in regard to respiration, although apparently not more so than with other anesthetics; and finally, that it affects the patient much less than ether or chloroform. The writer can, therefore, recommend it for general use. Its advantages are so great that it ought at least to have a fair trial and only be condemned for cause.

ATROPINE IN DELIRIUM TREMENS.

TOUVME (Vratch; Archives Médicales Belges; Gazetta Medica Lombarda, Sept 12), starting from the standpoint, based upon the researches of Mendel and Krukenberg, that in delirium tremens certain regions of the brain are in a state of depression, has tried various medicaments with a view to counter-balancing and dispelling the cerebral depression. He administered atropine to eleven alcoholics affected with delirium tremens, of whom five had the furious and six the calm type. In ten cases the patients became quiet shortly after a single injection and fifteen minutes later were asleep. The dose employed was one milligramme (about one-sixtieth of a grain) of sulphate of atropine subcutaneously. In one case alone, notwithstanding the administration of a larger dose of one milligramme and a half, the patient continued very restless. The injection was made in this case in the evening; in the
morning, after a cold affusion, the patient became calm. The following night he slept well.

Further, Touvime resorted to injections of atropine in a case of post-typhoid psychosis in a non-alcoholic. Two injections daily were given—namely, morning and evening—the dose being again one milligramme. The patient was completely cured in five days.

DIPHTHERIA IN LONDON.

In the Medical Press and Circular of October 12, 1898, Dixey tells us it is a fact admitting of no dispute, that whatever the cause, the case mortality of diphtheria in the metropolis has undergone a steady diminution since 1894, the year of the introduction of the serum treatment. In a paper to which he has already referred, read at the Carlisle meeting of the British Medical Association in 1896, he anticipated that by the end of that year the case mortality for the twelve months would, for the first time on record, have sunk below twenty per cent. This expectation, based on the course events were then taking, was quite borne out by the result, the proportion of deaths to notification for 1896 being, as will be seen on reference to Mr. Shirley Murphy's report lately published, only 19.3 per cent in 1896, as against 20.4 per cent in 1895, and 23.6 per cent in 1894. Since the date of the materials dealt with in that report, the figures for 1897 have become available, and it is satisfactory to find that the diminution in case mortality still continues, the percentage of cases to notification for last year having sunk to the comparatively low figure of 17.7. From a table, the data for which are derived from Mr. Shirley Murphy's report, partly from the Registrar-General's weekly returns, and partly from the monthly list of notifications published in the columns of The Lancet, the writer has found that this diminution in case mortality has progressed in spite of fluctuations in the number of both cases and deaths. It may be added that the experience of 1898, so far as it has gone, makes it probable that a still further reduction in relative fatality may be looked for. If any one doubts that this improvement in the case mortality of diphtheria is due to the introduction of the serum treatment, the writer thinks he may fairly be called upon to say what other factor can have been at work since 1894 capable of producing the present result. The fact of the diminution in case mortality cannot be disputed, and of this the more or less general adoption of the antitoxin treatment would seem to supply the most feasible interpretation.

THE USE OF MORPHINE IN BRIGHT'S DISEASE.

Sydney Ringer, of London, thus concludes a paper on this topic in the Journal of the American Medical Association of October 8, 1898. He says that Osler writes concerning uremia, "for the restlessness and delirium morphine is indispensable. Since its recommendation by Stephen Mackenzie in uremic states some years ago, the author has used this remedy extensively and can speak of its great value in these cases. He has never seen ill effects or any tendency to coma follow." Ringer's observations entirely confirm these statements, and yet the use of morphine in Bright's disease is denounced with little less than horror by most practitioners, though they all confess that they have never tried it—that, indeed, they dare not do so. Morphine hypodermically employed is of conspicuous benefit in the shortness of breath of uremia. This may be due to different causes. With some patients the compensatory hypertrophy gives way and they suffer from cardiac dyspnea, in all respects similar to that from valvular defects with insufficient compensation, notably sleep in aortic regurgitation. The paroxysmal shortness of breath prevents sleep; on falling asleep they are soon wakened by distress of breathing. The patient is compelled to start up in bed panting for air, or the sleep may be distressed and harassed by Cheyne-Stokes breathing. This distressing condition, whether due to deficient compensation in Bright's disease, or to valvular defects, is almost invariably relieved by hypodermic injections of morphine, and several hours' refreshing sleep are secured, to the great relief and comfort of the patient, who on the following day is refreshed, and takes, digests, and assimilates his food better. Morphine can scarcely be too highly recommended in such a condition, and although it does not cure, it delays the end and greatly lessens the distress of the declining days of life.

Uremic asthma, again, yields promptly to hypodermic injections of morphine. On the other hand, persistent distress of breathing may be due to dropsy, the lung being hampered by an abundant serous effusion into the cavity of the chest. It need scarcely
be said that such a condition is not improved by the use of morphine.  
The headache and sleeplessness occurring in uremic patients can generally be removed by the hypodermic injection of morphine.  The writer has not given this treatment in uremic convulsions or coma, but he has largely used it in many cases of uremia with other troubles, and is sure that morphine may be given to such patients with every prospect of benefit and no risk of harm.  

REPORT OF A DEATH FOLLOWING IMMEDIATELY AN OPERATION FOR NASOPHARYNGEAL ADENOIDS UNDER CHLOROFORM, WITH REMARKS ON CHLOROFORM ANESTHESIA IN THIS OPERATION.  

In concluding an article with this title in the New York Medical Journal of October 29, 1898, Hinkel tells us that the statistics show an exceptionally high mortality from chloroform anesthesia in the operation for the removal of lymphoid hypertrophies of the pharynx.  
The observations of the Vienna pathologists show that sufferers from "adenoids" frequently belong to an abnormal constitutional type that has been found peculiarly susceptible to chloroform narcosis.  
In view of the statistical and pathological data presented, the general use of chloroform in the operation for hypertrophied tonsils or nasopharyngeal adenoids is inadmissible.  

TYPHOID FEVER IN INFANCY AND CHILDHOOD.  

In a valuable article with this title in the Philadelphia Medical Journal of October 15, 1898, J. P. C. Griffith tells us that treatment need occupy but little of our attention, as there is little to be said that does not apply equally well to adult life. Medicinal treatment is purely symptomatic, as in adults, and is less often needed. Rest in bed is, of course, required, no matter how much the child wishes to be up. A milk diet is to be preferred. No purgatives should be given to overcome constipation, enemata being employed in place of them. With regard to the use of the bath, careful judgment is to be employed in giving it to children. Some do not bear the plunge at all well. This is particularly true of younger children. Certainly there is, as a rule, at no period of childhood the need to use water at as low a tempera
ture as in the case of adults. At the Children’s Hospital of Philadelphia it is the custom to employ the graduated bath, placing the child in the tub with the water at a temperature of 95° and cooling it down to 85°, or occasionally, with older children, to less than this. In nearly all cases this is quite as effectual as the cool bath, and much less likely to cause excitement from fright. Very frequently, indeed, sponging answers every purpose. Even a tepid bath may sometimes answer well. It must be remembered that many children bear elevated body temperatures remarkably well, as one of the cases detailed illustrates, and that the disease in childhood is likely to run a shorter course. We can, therefore, often afford to let the fever alone. If it is true of adults it is still truer of children, that hydrotherapy is not to be used as an unalterable plan of treatment, no matter what its effect, and merely because the temperature has reached a certain figure. If it is used according to any such method, it is capable, particularly in children, of doing often far more harm than good.  

ETHER NARCOSIS.  
The comparison of ether with chloroform as an anesthetic continues to be a subject of interest, and, in Europe especially, contributions to the journals upon this subject are frequent and often the results of long series of observations and experiments. In this country the popularity and reputation of ether seem to be fixed, and chloroform is almost everywhere regarded with some suspicion, in spite of some of its very attractive qualities. The very generally recognized disadvantage which ether has is undoubtedly the increased secretion of mucus and saliva which occurs during its administration. In the Archiv für Klinische Chirurgie, B. 57, 1898, Holscher gives some conclusions upon the action of ether, which are based upon a series of experiments upon animals. His paper is long, and his conclusions are that the ether vapor has very little irritant effect upon the bronchotracheal mucous membrane; that the tracheal râles during ether narcosis are caused by the aspiration of the secretions, salivary and mucous, from the mouth; that the affections of the air-passages following ether narcosis are caused by this aspiration; and that the increase in the flow of saliva depends largely upon local irritation by the vapor, but that central influences also play a part in this process.
It is a good thing to bear in mind that the secretions from the mouth are responsible for the tracheal râles, for it puts the prevention of the condition within the range of easy possibility, and also imposes a distinct responsibility upon the anesthetist. Of course patients are very variable in their behavior during etherization in regard to the amount of secretion and the character of the respiration, and in some it would be practically impossible to prevent the flow of some of the saliva and mucus into the trachea. It is probable, however, that it is only when the secretions reach the bronchi and their large branches that there is any great danger of pulmonary involvement. When the secretions do reach the large bronchi or the bronchioles and cause a bronchitis or a bronchopneumonia, the consequences are apt to be serious, especially in elderly or alcoholic patients.

Extreme care on the part of the anesthetist, both as to the amount of ether given and in keeping the mouth clean and the head and jaw in the correct position, is the only thing which can give us security from unpleasant experiences in a certain number of instances of the administration of this anesthetic. The dangers in the use of chloroform depend upon inherent poisonous qualities in the drug, and can be guarded against only by watching with extreme care the amount given and its effect upon the circulatory apparatus. Even with the greatest care cases will occur in which, on account of some latent cardiac trouble or of personal idiosyncrasy, alarming or fatal symptoms will develop, with very little time for satisfactory treatment.

In the case of ether, the dangers depend largely upon causes which are mechanical and can be prevented by mechanical means, leaving out, of course, any such event as the overwhelming of the patient with the drug, which should never occur and can only occur from carelessness. If the whole bronchial mucous membrane were pouring out an excess of secretion during etherization, it would be a very difficult matter to give the drug successfully; but if the secretion comes almost entirely from the mouth, it must be an easy matter to control.

In operations with tracheotomy, the presence of the tube in the trachea is irritating and causes an extra secretion of mucus in the trachea; and if this secretion becomes mucopurulent and the inflammation extends downward, the consequences are self-evident. In ordinary etherization we have not this source of irritation, and whatever sepsis is introduced must come from the mouth.—Medical Record, Oct. 22, 1898.

**THE PREVENTION AND TREATMENT OF TRACHOMA AT THE HOUSE OF REFUGE.**

From a large experience in an epidemic of trachoma Gilfillan concludes that it is best to divide trachoma, clinically, into three forms, or classes:

The mild cases, where only the lower lids are involved. In these cases the patients are often not aware that they have any trouble with their eyes. On examination one finds a dozen or more granules on the conjunctiva of the lower lid. There is slight lacrimation, but no other symptom.

Ordinary cases, where both the upper and the lower lids are involved. In these the appearance of the conjunctival surface of the lids is like a nutmeg grater, being studded irregularly with granules. Lacrimation and sticking of the eyelids together in the morning, besides a rough feeling of the eyes as if something were in them, are present in these cases.

In chronic cases the granules have broken down, leaving the conjunctiva in appearance red, velvety, and succulent. Lacrimation and photophobia are marked symptoms. Oftentimes there is a growth of blood-vessels on the cornea.

Of his three hundred and twenty-five cases of trachoma, at least a hundred and fifty were of the first class. Many of them were very mild, the disease having only just begun. Every night and morning half a dozen drops of the following solution was instilled into the eyes in this class of cases:

\[
\begin{align*}
\text{Tannic acid, } & 7 \text{ j;} \\
\text{Glycerin, } & 13 \text{ j.}
\end{align*}
\]

M. S.: Eye drops. Use twice a day.

Three times a week an application of sulphate of copper crystal (bluestone) was used on the everted lids. Often this was replaced for a time by the use of alum crystal (white- stone). All of this class did well and soon recovered. To show how fast they were discharged cured he appends a statement. When necessary he used Knapp’s roller forceps.

After this operation an application was made twice a day with a camel’s-hair brush to the everted lids of a 1-to-6000 bichloride solution. This was kept up for three weeks. Three times a week the application of the bluestone was also made.
Most of these operative cases are cured in from three to six weeks. Sometimes it is necessary to operate a second time in cases where there are large masses of granules. As a rule, the prognosis in the first and second class of cases is good.

**INDICATIONS FOR THE APPLICATION OF THE OBSTETRICAL FORCEPS AT THE PELVIC OUTLET.**

In the *New York Medical Journal* of October 29, 1898, Root tells us that the time to apply the obstetrical forceps at the pelvic outlet cannot be governed by fixed rules. This must rest with the operator, and requires a nicety of judgment gained only by careful study of each individual case. In skilled hands the application of the forceps is better made too early, or earlier than is absolutely necessary, than too late, for too late means disaster to mother and child. It is not possible to draw distinct lines for indications, but for convenience of study we may divide them into five groups:

The fault lies wholly with the *vis a tergo*; the head is more or less movable, and there exists no obstruction in front of the head: (a) the pains or uterine contractions are inefficient; (b) the umbilical cord is short.

Cases where the anteroposterior diameter of the head, though presenting, fails to engage in the corresponding diameter of the outlet, the head being more or less movable. Large head with (a) occiput anteriorly; (b) occiput posteriorly.

To produce complete flexion in a partially extended head that cannot be flexed by the expulsive forces without undue duration of labor or by the hands of the accoucheur, the head being more or less firmly fixed.

To shorten the second stage of labor for the relief of maternal suffering.

For the immediate relief of the child.

When uterine contractions are inefficient there is a want of expulsive force exerted upon the fetus. The cause may rest with the uterus itself; it may arise from the delicate muscular and nervous organization of the patient; from impaired health, as in cases of albuminuria, or wasting disease; and from weariness produced by a prolonged first stage.

When there is a short cord or a cord shortened by coils about the neck. In this group of cases the head moves forward and recedes without material advancement. The to-and-fro movement of the head is especially marked in cases of short cord. The recession of the head differs in character from recession following relaxation of a uterine contraction or of expulsive efforts. It has more the appearance of being pulled back, and the shorter the cord the more marked is this characteristic, which may be considered diagnostic. The cord shortened by coils about the neck will produce a similar effect. When the conditions under (a) and (b) exist, the natural rhythm of the pains is soon disturbed or destroyed. The pains become short in duration and "choppy" in character. The expulsive efforts are unsteady and ineffectual.

It is worse than folly to allow these conditions to exist longer than is necessary to determine their existence.

In this group of cases the application of the forceps is easy, and extraction should be attended with little or no danger or added suffering to the mother, except in cases of short cord. Hence the danger is chiefly to the child. The cord may be torn from the umbilical ring or the placenta may be prematurely loosened. This danger is not light, and may be obviated to a certain extent if a skilled assistant will use abdominal pressure over the uterus to facilitate its descent with its contents into the pelvis.

In this group the difficulty lies in front of the head and not behind it. There exists some disproportion between the head and the birth canal, due to oversize or faulty position of the head or to undersize of the outlet.

The pains are strong and the expulsive efforts are well directed. But all efforts meet with defeat because of the opposing diameters of the bony outlet. The sphere of their circumference is filled by the presenting portion of the head when advanced by a contraction. The head fills the space in proportion to the compression it has undergone.

The caput succedaneum extends beyond the tuber ischii and protrudes from the vaginal orifice. Each effort at expulsion will seem to promise delivery of the head, but examination will find the parietal bosses behind the tuber ischii and the inion behind the symphysis pubis. The anteroposterior diameter of the head that is presenting is too long to allow the inion to pass from under the pubic arch or over the perineum if it is posterior. During the absence of pain the head recedes—freely if the cavity of the pelvis is roomy, and less so if not.

The movement of pseudoextension ob-
served when the head is pushed down by a contraction, and which so often deceives the inexperienced or careless into believing that the head is advancing, is due to the head revolving slightly upon its transverse diameter in the effort made to pass the outlet. The gradual increase in the size of the caput succedaneum adds to the deceptive promise of delivery made to the disheartened patient.

Vigorous efforts, voluntary and involuntary, will continue according to the strength and endurance of the patient, but they will sooner or later assume the characteristic behavior of expulsive efforts that meet with obstruction. If relief is not given the patient begins to show signs of exhaustion. The uterus becomes irritable and sensitive to the touch; pains are excruciatingly painful and "choppy," overthrowing the equipoise of the patient's nervous system. The soft parts become swollen, contused, and edematous, while the child dies or is born in extremis.

No case should be allowed to reach this pitiable and dangerous stage before relief is given. The diagnosis should be made early. The changed character of the pains, and the behavior of the patient while under their influence, should give early warning to the accoucheur of what lies before him. The forceps should be applied and delivery effected before signs of exhaustion begin. Greater traction force is needed here than in the first group, with proportionately greater compression of the head.

The integrity of the perineum and the lower third of the vagina are greatly endangered; laceration is more than likely to occur, and is inevitable if the ision is situated posteriorly, unless the head is very small.

To produce flexion of a partially extended head that is more or less firmly fixed. The conditions that give rise to this form of dystocia usually occur in the cavity of the pelvis.

The cases the author includes in this group are those where rotation has taken place or is nearly completed, so that the application of the forceps to the sides of the pelvis applies them to the sides of the head. This form of arrested head usually occurs just within the outlet. It is chiefly due to a hand of the fetus falling under the chin, or some other displacement of an arm that prevents flexion. The fetus is crowded into the pelvis by the uterine contractions, and by retractions when the fruit-water is spent. The forceps applied, traction is made horizontally until the head reaches the floor of the pelvis and presents well at the outlet.

The advance of the head gives the chin a chance to escape the obstructing hand or arm, when flexion is readily accomplished by lowering the occiput if in front and raising it if posteriorly. After flexion is produced delivery of the head in anterior positions is easy, with or without the further use of the forceps.

The diagnosis of this difficulty is not easily made, and must be largely presumptive.

In cases where the diagnosis may be reasonably assumed, the inlet is wide and the cavity fairly roomy. The adjustment of the forceps blades points to the difficulty. One blade will slip easily into place, while its fellow will meet with an obstruction that prevents it from reaching home. This can be due to the tip of the advancing blade coming in contact with the shoulder of the same side that has been driven into the pelvis and passed the side of the face. The projecting hand fills the groove between the shoulder and the side of the face. It is then difficult to insinuate the tip of the blade between the shoulder and the side of the face, but when this is done the hand or arm is pushed away and the blade slips home. Difficulty in adjusting the tip of one blade, followed by ready flexion and delivery, should point to a displaced hand or arm.

The forceps is indicated for the relief of maternal suffering. The greatest danger from its use for this purpose arises from the resistance of the perineum terminating in its rupture. Whether the cause lies in the vis a tergo, the vis a fronte, as supplied by the forceps, or in both combined, the too rapid advancement of the fetal head endangers the perineum. In this group of cases the vis a tergo is efficient, the patient is in good condition; there is no obstruction offered the advancing head except that of a slowly dilating perineum. But the patient suffers and frets under the burden of pain laid upon her. To relieve her the forceps is applied; but it must be remembered that traction by means of the forceps lends added power to the force behind. If these combined forces are out of proportion to the dilatation of the soft parts, rupture is inevitable and unnecessary damage is done.

If the time for applying the forceps is rightly chosen and the forces in hand are well controlled, we may expect the happiest results. We may not only escape a possible rupture from bad use of the forceps, but may prevent a probable rupture if the case had been left to spontaneous delivery.

The period of suffering may be shortened
from half an hour to two hours with absolute safety and comfort to both mother and child. At no time, other things being equal, should this boon be denied the patient.

A forceps operation is usually undertaken for the greater safety of mother and child. In this group we choose to deal with those cases in which the child alone is considered: (a) When the child is debilitated and small and is not likely to withstand the vicissitudes of labor, though of average duration; (b) when the mother gives the history of having borne children that have died during labor, pending spontaneous delivery, or soon after; (c) when the head has been upon the perineum, under pressure long enough to jeopardize, or better, before it jeopardizes, the life of the child; (d) in cases of hemorrhage in partu. An escape of blood during an intermission of pain and recession of the head points to a premature separation of the placenta, or laceration in some portion of the birth canal. When this occurs, little time should be lost in determining the site of the hemorrhage. If not found in a laceration, we must act upon the supposition that the hemorrhage is placental and apply the forceps. The integrity of the perineum should be of secondary consideration, for a wound well repaired will heal more easily than life can be restored to the child.

INJURIES OF THE GALL-DUCTS.

Porter (American Journal of Obstetrics and Diseases of Women and Children, November, 1898) deals in his communication only with the cystic right and left hepatic and common duct, and more especially with the common duct because its great length and less protected position render injuries to it more frequent than injuries to the hepatic ducts, while injuries to the cystic duct present no features differing in practical import from injuries of the gall-bladder.

The general direction of the common duct is downward along the right border of the lesser omentum to the inner side of the descending portion of the duodenum, where it empties by piercing the walls of the gut obliquely, thus making the opening valve-like in action. Just before piercing the gut the common duct receives the duct from the pancreas.

By passing the finger from left to right along the lesser omentum until the right margin is reached, then hooking the finger under this margin through the foramen of Winslow, the common duct may be lifted forward. The common duct lies in front of the vena portae, to the right of the hepatic artery, and is crossed in front by the pyloric and gastroduodenal arteries. The superior pancreatico-duodenal branch of the latter artery lies in close relation to the right side of the lower two-thirds of the common duct. It is important that the changes in the position of the liver and the consequent changes in the position, direction, and relations of the ducts, due to relaxation of the abdominal walls, etc., be borne in mind.

Injury to the hepatic ducts is usually accompanied by injury to the liver also. This does not apply, of course, to those cases in which the injury is produced, either intentionally or by accident, in the course of operations. One would expect injury to the common duct to be complicated usually by hemorrhage, owing to the close relation it bears to numerous large blood-vessels; but this does not seem to be the fact, judging from the few cases reported. This may be accounted for by the relatively greater power of resistance of the blood-vessel walls.

No case of rupture of the gall-bladder or gall-ducts without penetration of the abdomen is reported in the “Medical and Surgical History of the War of the Rebellion.” The cases reported show the most frequent cause to be forces which act in a crushing manner, such as a blow on the abdomen or the passage of a wagon wheel over it. The presence of gall-stones predisposes to rupture of the gall-ducts from trauma, and their presence may cause ulceration and perforation.

The symptoms, mentioned in the order in which they usually occur, are pain, shock, ascites, acholia, jaundice, and other symptoms of choleemia, peritonitis, and inanition. Pain is usually severe, and most marked in the right hypochondrium. The pain may, however, be severe in other regions of the abdomen without there being any signs of injury to account for it, and slight or entirely absent in the region of the ducts.

Shock is generally pronounced and the reaction therefrom rather slow. So-called secondary shock or unduly prolonged shock means hemorrhage and demands immediate celiotomy. It is possible for the shock to prove fatal in these cases through injury to the solar plexus.

In cases where the lesion is of such a nature as to divert nearly or quite all of the bile from the intestine into the cavity of the
peritoneum, ascites develops rapidly. Estimated the daily quantity of bile at two and a half pounds, as given by Flint, we can appreciate the diagnostic importance of this symptom. In a case of rupture of the gall-bladder reported in Holmes' "System of Surgery" (vol. ii, p. 419), marked distention of the abdomen was noted two days after the injury. In the writer's own case it was not noticed by the attending physician until about a week after the injury, but it recurred to the extent of ten pints in four days after tapping. The ascites is usually general, but may be localized by the formation of adhesions or by the filling of the lesser cavity of the peritoneum. This latter would be more likely to occur in cases of rupture of the common duct at the margin of the foramen of Winslow. Filling of the lesser cavity of the peritoneum with bile would produce an ascites of the upper abdomen, which would soon become general unless the foramen of Winslow were closed. The ascites may be general at first, and, after tapping, become localized.

The degree of acholia will depend upon the completeness of the diversion of the bile from the intestine, and is therefore incomplete in rupture of the cystic duct, of either of the hepatic ducts, and in small perforations of the common duct. This is also true of jaundice, and, indeed, of all symptoms which are due either to the absorption of the excretory elements of the bile or to the absence from the intestinal canal of the secretory elements of this fluid.

Jaundice is more likely to occur in those cases wherein the escape of the bile into the peritoneal cavity is preceded by obstruction of the bile ducts, and in those cases in which the bile within the peritoneal cavity is subjected to pressure. Jaundice is not a constant symptom of escape of bile into the peritoneal cavity.

If the ducts are healthy at the time of injury the principal source of infection is the bowel, through regurgitation along the duct. Other things being equal, the danger of infection from this source increases in proportion as the injury approximates the bowel. However, the valve-like character of the opening of the duct into the bowel renders infection from this source less likely than one might on first thought suppose.

Bile, if aseptic, will not produce peritonitis. Practical experience has shown that the fear surgeons formerly entertained of bile within the peritoneal cavity is unfounded. Lane re-ports a case of rupture of the gall-bladder, which recovered after operation, in which for five weeks a considerable quantity of bile was present in the peritoneal cavity.

In case the bile is completely diverted and the patient lives long enough, symptoms of inanition will develop.

Fatty stools seldom occur. This condition of the stools, together with other signs and symptoms of faulty digestion, would no doubt be more likely to arise in cases where the rupture occurs close to the opening of the pancreatic duct, as in such cases there might be escape of the pancreatic juice into the abdomen.

Mental hebetude, peevishness, subnormal temperature, and slow pulse are usually present. If peritonitis supervenes the pulse will be quickened and the temperature will rise, but not in the same degree as would occur in an equally severe peritonitis from other causes.

Marked infection may be present with slight or no elevation of the temperature and very little acceleration of the pulse. This influence of choleemia on the pulse-rate and temperature in the presence of infection is an important clinical fact.

A satisfactory diagnosis cannot be made without opening the abdomen. Exploratory celiotomy should be promptly done in all cases of injury to the abdomen in which the symptoms are such as to arouse any suspicion of serious injury to the abdominal contents.

Cholemia, acholia, and infection are the conditions to be avoided or remedied. Perfect drainage will obviate the first and last, but to obviate the danger arising from acholia we must devise some means by which at least some bile may get into the intestinal canal.

Cystectomy with closure of the duodenal end is the method of choice in cases of rupture of the cystic duct. If accessible the rent may be closed by sutures. In rupture of either hepatic duct it may be possible to close the rent by sutures; but in most, if not all, cases of complete division of the duct the use of gauze drainage or combined gauze and tubular drainage will be the only feasible method of treatment. To this it would perhaps be well to add ligature of the duct on the duodenal side of the rent. This will lead to a permanent biliary fistula if the patient survives, but the danger from acholia would perhaps not be great, and we can scarcely hope for a reestablishment of the flow of bile.
through the normal channel under these circumstances. If the perforation be small, it may close and the patient recover if drainage be established. Landerer's case recovered under repeated punctures. Kernes' case recovered after the abdomen was opened, dried, and then closed without drainage.

Injuries of the common duct, when they result in complete diversion of the bile from the intestine, are inevitably fatal, unless by some means the diversion be overcome. That large quantities of bile may be discharged through abdominal fistula for an indefinite period without harm to the individual is, of course, a matter of frequent experience, but the writer knows of no case which disproves the statement that complete diversion of the bile from the intestinal canal is, if not remedied, fatal. Small openings in the common duct may be sutured, or, if this is not feasible, they may be treated with drainage, in the hope that the opening will close spontaneously.

When, from an examination through an abdominal incision or from an examination of the stools, it is learned that no bile is flowing into the bowel, no time should be lost in reestablishing this flow. End-to-end approximation of a completely divided common duct by suture or other means is possible, perhaps, in some cases.

If both ends of the divided duct can be found, the best method to adopt would be ligature of the bowel end and implantation of the liver end into the duodenum. A method less ideal, no doubt, but more often practical, would be closure of both ends of the divided duct, in case they can be readily found, and choledochectomy. In case the injury to the duct cannot be easily found, and the condition of the patient is such as to demand that the operation be done quickly, it would be best, perhaps, to do a choledochectomy and use a gauze tampon for the double purpose of establishing drainage and encouraging the flow of bile through the newly formed channel, and thus hasten the closure of the rent in the duct. If haste is not essential the union of the gut and gall-bladder may be made by suture; but, in many cases, to save time is to save life, and for this reason the use of the Murphy button is advised in all cases where speed is essential.

In choledochectomy with closure of the common duct it is important that the anastomosis be made as high in the bowel as is possible, in order to avoid fatal or serious acholia. Cases will present themselves now and again in such deplorable condition that radical operation will be out of the question. Under such circumstances the operation should comprise the doing, in as quick and simple a way as is possible, of those things only which are immediately necessary to save life, such as the establishment of drainage when life is threatened by peritonitis, or the use of gauze packing for hemorrhage. The immediate danger having been averted by these measures, a radical operation may be done later on when the patient is better able to stand it.

Theoretically one would seem warranted in expecting much relief from the symptoms due to the absence of bile from the intestines from the administration of inspissated ox-gall and salol, or other intestinal antiseptic, together with the use of predigested (emulsified) fats; but in the reported case the use of salol and ox-gall seemed without effect. No emulsified fats were given, as no fat was seen in the stools.

In conclusion the author emphasizes the following points:

Fatal inanition may be caused by an injury which results in a complete diversion of the bile from the intestines.

Jaundice may be absent though a large quantity of bile is thrown into the peritoneal cavity.

Cholelithiasis and inanition combined may keep the pulse-rate and temperature normal, or even below, in the presence of marked asepsis. Acting singly these conditions have the same effect, but in lesser degree.

Jaundice is not always present in cholelithiasis. Porter concedes that the truth of this last proposition may be open to question, but the burden of proof rests with those who deny it. The other conclusions are, in his opinion, supported by evidence that is incontrovertible.

A SIMPLE TREATMENT DIRECTED TO THE RELIEF OF THE LOCAL CONGESTION INCIDENT TO PROSTATIC HYPERTROPHY.

NOGUES (Annales des Organes Géniro-Urinaire, quoted by Monatshefte für Praktische Dermatologie, Bd. 27, No. 8), after stating the well known fact that congestion of the prostate rather than absolute enlargement of this gland is often responsible for obstruction to the passage of the urine, urges as a means of combating this congestion regulation of
the circulation, systematic evacuation of the bladder, and abdominal massage. The results of this latter procedure were extremely satisfactory, especially in the early stages of prostatic enlargement and urinary obstruction. The acts of micturition became painless and were much less frequent, especially during the night. Even in cases of complete retention massage seemed serviceable, since the urine became clearer and there was less bleeding.

ESSENTIAL RENAL HEMATURIA.

De Bairieux (Annales des Société Belge de Chir.; Annales des Organes Génito-Urin., No. 9, 1898), stimulated thereto by a case of rebellious hematuria dependent upon a chronic unilateral nephritis reported by Keersmaeker, contributes the interesting details of a woman twenty years old who in April of 1895 presented herself with a history of having suffered from hematuria for six months. This began with an attack of grippe, and was accompanied by pain in the left side of the belly, the iliac fossa, the lumbar region. This pain was habitual, though not constant, and was sometimes severe enough to prevent sleep. Occasionally it presented the features of true nephritic colic, running along the course of the ureter toward the labia majora, being accompanied by nausea and vomiting. At times this was so intense as to cause the patient to faint.

There were not the classical symptoms of stone, there were no pus cells, nor tube casts in the urine, nor crystals of any kind. The reaction was faintly acid and the albumen was exactly proportionate to the quantity of blood. The urine was sterile; there was no polyuria; occasionally perfectly limpid urine would be passed—once it remained so for two days.

The renal origin of the blood was decided upon because of the absence of all vesical symptoms and the presence of pain and tenderness in the region of the kidney. The urine passed in three glasses showed an equal quantity of blood in each. On irrigating the bladder the fluid returned without trace of blood. After having irrigated the bladder and removed the catheter, bloody urine could be drawn five minutes after.

Diagnosis rested between neoplasms and calculus. It was decidedly in favor of the latter. On operation the kidney was found normal in appearance, dimensions, and position. The kidney was split and nothing abnormal was found. The kidney was sewed and the wound closed. From that time bleeding ceased, and the patient has been perfectly well ever since.

The second case bled for five months, and was opened by Broca. The kidney was found healthy and was sutured in position. The bleeding ceased immediately.

The third case, having suffered in 1878 from symptoms of nephris, passed bloody urine from that epoch until 1886, when Sabattier, believing a calculus was present, practiced nephrectomy. The kidney removed was perfectly healthy. Hematuria ceased after operation and the patient was well more than a year later.

Another patient suffered from hematuria in December of 1887. This was followed by apparent cure, but in 1889 the hematuria recurred and was almost continuous. Because of the history Senator diagnosed hemophilia; Nitze demonstrated that the blood came from the right ureter. In 1890 Sonnenberg practiced nephrectomy. Histological examination showed only very small isolated portions of the kidney affected with interstitial nephritis. Hemorrhage ceased after the second day following operation. Seven months later the patient was still well.

These four cases were all women.

The fifth case, that of a man aged fifty, suffered from abundant hematuria after taking a cold drink; at first intermittent and relieved by rest, it finally became continuous and exhausting. A slight pain in the left side furnished the indications for operation. Nephrectomy was practiced. The left kidney, though anemic, was perfectly healthy. The patient got well.

The sixth patient was a sailor, who suffered over twelve years from hematuria associated with pain in the left kidney. Lauenstein performed pyelotomy, hoping to find a stone, but in this he was disappointed. The patient recovered and had no recurrence of bleeding.

The seventh case suffered over five years from nephritic colic of the right side and hematuria. For two years it had become continuous. Abbe practiced nephrectomy, introduced his finger into the pelvis, and found only the extremity of one pyramid covered by a light gritty deposit, which was scraped away. After the fourth day hematuria ceased and never recurred. Pain was also relieved.

Many other cases are reported of both nephrectomy and nephrectomy, all failing to show any adequate lesion in the kidney.

The bleeding seems to be dependent upon
an obscure anatomical condition, one which cannot even be detected by minute microscopic study of sections of the kidney substance. The condition has been termed essential renal hematuria or renal hemophilia. The characteristic of this form of hematuria is that it is associated with no demonstrable anatomical lesion, that it is refractory to all medication, and that it disappears either spontaneously or as a sequel of an operation the efficacy of which cannot be clearly explained.

The theory that the bleeding is due to an angioneurosis finds its support in the fact that this condition is much more frequent in women than in men; also operations other than those performed on the kidneys are followed by a cure of the affection. Thus Passet and Picquet, having through a mistaken diagnosis performed hypogastric cystotomy, cured the patient.

As to the treatment of this affection nephroty is the operation of choice, followed by nephrectomy if the kidney is markedly diseased.

THE RADICAL TREATMENT OF PROSTATIC HYPERTROPHY.

Fuller (Medical Record, Nov. 19, 1898) thus describes his operation: The patient is placed flat on his back, neither the Trendelenburg position nor the Petersen bag being commonly found necessary. The bladder is carefully washed out, and then left moderately distended, to the extent of from eight to twelve ounces. The next step is to open the bladder suprapubically. The forefinger of the left hand is then introduced into the bladder, the location and extent of the prostatic obstruction are determined, and the vesical opening of the urethra is located. In the right hand is grasped a pair of serrated-edged scissors with a long handle. These scissors are slipped along the left forefinger to the urethral opening, and are made to cut through the bladder wall in that region. The cut extends from the lower margin of the internal vesical opening of the urethra backward for an inch to an inch and one-half. The blades of the scissors being rough and serrated, make an incision which bleeds but little. Then one of the forefingers, whatever the operator may find the more convenient, is slipped through the vesical hole made by the serrated scissors, while at the same time the fist of the other hand makes firm counter-pressure against the perineum. By means of this counter-pressure the prostatic growth is brought well into the reach of the forefinger, which is employed all this time in enucleating the prostatic obstruction, en masse or piece by piece, as the case may be. The enucleation can be easily and speedily accomplished in this manner, and should not be desisted from until all the lateral and median hypertrophies, as well as all hypertrophies along the line of the prostatic urethra, have been removed. The vesical walls at the base, as elsewhere, are very elastic and dilatable, so that it will be found that the little cut made through the bottom of the bladder will be large enough to admit of the passage through it of the enucleated prostate.

A perineal section is then made, and a large-sized (No. 26 American) soft-rubber tube is passed through the perineal cut, and the cut through which the prostate was enucleated, into the bladder. After this, hot-water irrigation is employed for some minutes, to wash out blood-clots and to stop oozing. Then the suprapubic wound is closed by a deep layer of catgut sutures, which include the bladder wall, and by a more superficial layer of silkworm-gut (Florentine) sutures. About in the middle of the cut the catgut stitch is omitted and a deep Florentine-gut suture is taken, which includes the vesical wall and the whole extent of the lateral abdominal wall: This suture, however, is not tied at the time of operation, thus allowing a rubber suprapubic drainage tube to remain temporarily in position. At the end of four or five days this suprapubic drain may in most instances be removed; then this last Florentine ligature can be tied, thus entirely closing the suprapubic cut. It is best not to remove these Florentine sutures till after the patient is up and about, as without their firm support there is oftentimes a tendency for the soft scar tissue of the wound to give, thus allowing a considerable spreading of the abdominal structures.

Some hypertrophies will be encountered which do not admit of enucleation by the finger in the manner described, owing to the abundance and denseness of the fibrous tissue helping to constitute them. In such instances the writer has found it necessary to introduce prostatectomy forceps through the hole made in the vesical floor, and, after seizing a piece of the hypertrophy, to twist it free. If sufficient tissue is not removed by the first twisting, the instrument should be reintroduced, and so on, till all obstruction has been taken away. On one or two
occasions the writer has encountered tissue so dense and adherent to the vesical wall that the forceps and the twisting process have seemed dangerous, owing to the force they would necessitate. In such unusual cases the tissue should be cut away, and for that purpose the writer recommends Jessop’s prostatic scissors. He also favors two supravaginal drainage tubes instead of one, following the example set by Guyon in the after-treatment of cases in which vesical growths have been removed suprapubically.

In order to save time, and also because he finds them unnecessary, the writer has discarded the layer of catgut sutures and now employs simply the one layer of silkworm-gut to close the wound. One of these sutures after passing through all the abdominal layers includes also the bladder wall at the upper portion of the vesical incision, while another one in like manner includes it at the lower portion of the incision. In this manner the vesical is kept up in close apposition to the abdominal wall, so that there may be no escape of extravasated fluid into the space of Retzius. In doing this operation the author very rarely ties a blood-vessel, thereby saving considerable time. In order to be able to perform prostatectomy of this description with neatness and despatch, a surgeon should have good control of his forefinger and be possessed of some strength of wrist and forearm.

The writer finds the records of twenty-seven personal cases of prostatectomy, most of which were subjected to his method. These cases he has divided into two classes: those in which all the larger surface arteries were felt to be markedly atheromatous, and those in which such changes were absent or not prominently evident.

Five of the writer’s cases come under the first heading, and twenty-two under the second.

Out of the five patients of the first class three died after operation. One of them, who was apparently progressing favorably, experienced a severe seizure of cerebral apoplexy on the third day. In another, the post-mortem showed extensive postoperative hemorrhage into the space of Retzius and underneath the peritoneum, occasioned by the calcareous condition of the blood-vessels. The other died suddenly on the fifth day, perhaps of thrombosis.

Out of the twenty-two cases of the other class two died—one of suppression and shock, and the other of peritoneal symptoms, but of just what nature, in the absence of autopsy he could not determine. Many of these latter cases were very bad apparent risks. Some of them were operated upon in emergency, it being impossible to relieve the bladder except by aspiration. Most of them were suffering also from the effects of vesical infection, and in a good percentage of these cases the infection had ascended to the renal pelvis.

Two cases, both earlier ones, passed from Fuller’s view with suprapubic fistula. They were careless individuals from the lower social strata. He does not feel that such an after-lesion need be reckoned upon as at all likely or necessary, provided a patient cooperates with the surgeon. A postoperative inconvenience sometimes complained of, and which is usually of temporary duration, is the loss of a drachm or so of urine when there is some vesical pressure as a result of bodily activity. In one instance vesical incontinence persisted after operation, due, he is inclined to think, to chronic sclerosal peri-vesical inflammation. As a result of his experience he would avoid operating on individuals of the first class except for the relief of suffering, since the chance is against their recovery. The value of the operation, with reference to the other class, speaks for itself.

**THE OPERATIVE TREATMENT OF CLEFT PALATE.**

Owen (British Medical Journal, Nov. 5, 1898) says that the observations in connection with the operative treatment of cleft palate arrange themselves under three headings: (1) Before the operation; (2) the operation; and (3) after the operation.

The operation not being one of immediate urgency the surgeon can choose his time for it, making such preparations as will, if efficiently carried out, add greatly to the prospects of securing a completely successful result.

Thus, if the child is brought looking ill or poor, if it is found on inquiry to be liable to severe attacks of diarrhea, or to cough, or to vomiting, the operation must be put off and attention directed towards procuring the general and particular improvement of the child. If the tongue be foul and coated, a change of air and diet should be ordered, and the child put upon a course of rhubarb and soda mixture, which has a most beneficial effect in the treatment of chronic dyspepsia in children. Particular attention
should always be paid to the teeth. Every carious tooth should be extracted, or cleaned and filled, and to diminish to the utmost the risk of the line of the suture in the palate becoming infected from the pathogenic microorganisms the mouth and gums should be for some days washed over with a saturated lotion of boracic acid with glycerin.

No one would propose the performance of a plastic operation upon the hand, for instance, until the area of operation and its neighborhood had been rendered aseptic, and although it is not practicable to effect as much in regard to the mouth, still the surgeon should accomplish his utmost in that direction. It is usually found that there is something for the dental surgeon to do before the mouth is in a condition to invite the performance of a staphylorrhaphy.

With regard to the important matter of the presence of pharyngeal adenoids and of enlarged tonsils, it is sometimes advised that the operation upon the palate should precede that upon the tonsils and adenoids, but such advice is not sound. The child has hitherto been in the habit of breathing through a wide palatine cleft, and if this is suddenly closed by operation provision should surely have been made for securing a passage for the air as free as possible; and we know how seriously the airway may be blocked by tonsillar and adenoid disease. The surgeon should amputate enlarged tonsils at least ten days before dealing with the palate, and if, on doing so, he cuts across a septic or tuberculous focus, as often happens, he had better wait a little longer still before dealing with the palate; and when adenoids are conspicuous through the cleft, it is surely better that they should be scraped away before operating on the palate.

Just before the operation on the palate the nurse should give a beef-tea enema with a little brandy.

The anesthetic is chloroform, administered partly by a mask and partly by a Junker's apparatus, but the child should not be too deeply under the anesthetic. It surely must be an anxious time for the anesthetist when the operator keeps on insisting that the child is not sufficiently comatose. The child should now and then show signs of "coming round."

When the child is fairly under the anesthetic a strong suture is passed through the tip of the tongue, which is well pulled out before introducing the gag; in this way it can best be kept from rolling back against the soft palate when the hindmost part of the cleft is being dealt with. The child is then brought up to the end of the table and its head allowed to hang back so that the blood may have but slight chance of finding its way into the larynx.

As soon as the edges of the cleft have been denuded, an incision is made along the inner side of the alveolar process, and as this is apt to be followed by a good deal of bleeding it is well to pause here for a few moments and make firm pressure with a sponge so as to keep the bleeding under control. Then the raspatory is introduced, and the mucoperiosteal flaps are raised. But, as a rule, they cannot be shifted towards the middle line, and be sutured there without tension, until the alveolar incisions have been prolonged backwards into the soft palate. These incisions, which should be quite free, traverse the attachments of the levator and tensor palati, as well as that of the palatopharyngeus. Then the attachment of the aponeurosis of the velum to the posterior border of the hard palate is divided with the curved scissors and the sutures are inserted. For the sutures Owen uses almost entirely silver wire, supplemented in some cases with horsehair. The wire sutures are inserted by a modification of Smith's needle, which is also made by Weiss. In the case of a complete cleft he inserts about ten or a dozen sutures.

A point of great practical importance is to have the lateral incisions made very freely. Indeed, the author makes them so free that, as the palate is being sutured, he uses them for the introduction of small pieces of sponge for removing blood from the front of the nasopharynx, and after the operation they together seem to be as wide as was the original cleft; inasmuch that onlookers have sometimes asked if there is no fear of the flaps sloughing, or of the incisions falling to be obliterated. In neither of these respects, however, has there been any trouble.

The operation as thus described is extremely simple. It demands the use of no rectangular knives for the separation of the mucoperiosteum, and the expansions of the muscles into the soft palate are divided by a simple, straight incision. One great point in the operation is to have the edges of the palatine flaps adjusted without any tension whatever. The effect of tension after any surgical operation is apt to be disastrous.

Probably the child will vomit when he is "coming round," and if he does this just be-
fore he is moved from the table, so much the better. The act of vomiting does not in the least interfere with the line of suturing, as the writer has often assured himself, though, of course, if vomiting persists it may be prejudicial. The nurse must be told not to be surprised if the fluid ejected from the stomach is blackened by blood which has been swallowed. When the child is put back to bed his head should be slightly raised on a pillow, with the face turned down so that the blood-stained saliva may escape from the mouth and fall into some absorbent material.

Whether the mouth spray is used or not, a case every now and then goes wrong after operation. The child looks ill; his temperature runs up a degree or two; his tongue is coated; his breath is foul; the line of the palatine suture becomes swollen and unhealthy; and a thick, stringy, mucopurulent discharge collects about the roof of the mouth. The appearances are ominous and unmistakable. What has happened is that staphylococci have taken possession of the damaged tissues, and undergoing cultivation are spoiling or completely wrecking the surgeon’s handiwork. The writer has at the present time an operation case of this sort in the Hospital for Sick Children. It was in a girl, with a complete cleft (and rather a wide one) of the soft, and of the whole of the hard, palate. Mr. Templeton took a thrust cultivation from it on the seventh day, and found the gelatin completely liquefied by vigorous staphylococci in less than thirty-six hours.

To say that Owen allowed the infective disease to run its course feebly expresses the truth; he could not stop it. But a fortnight after the original operation, when the sullivan and swollen edges of the cleft began to look bright and clean, he had the child again under chloroform, and, having freshened up the marginal granulations, he brought the edges of the flaps together once more, and secured them by wire sutures, which he inserted quite wide of the cleft. To get the edges together without tension he introduced the raspatory once more by the lateral incisions, and again freely raised the mucoperiosteal flaps. The case has done extremely well, and it seems to promise as good a result as if the edges had adhered by primary union. This, indeed, is the chief point of his paper, and he regards it as one of great practical importance.

There is no factor so prejudicial to prompt union after staphylorrhaphy as septic infection, but after a child has undergone this infection we should probably be right in concluding that he could not undergo a second attack; that he has acquired by it a complete immunity.

THE COMPLICATIONS OF OPERATION FOR THE REMOVAL OF THE APPENDIX.

Dr. R. A. Sterling (Intercolonial Medical Journal of Australasia, Aug. 20, 1898; New York Medical Journal, Oct 15, 1898), in his third clinical lecture on the “Treatment of Acute Appendicitis,” thus tabulates the more frequent complications that may upset all plans of treatment, even in the presence of the most careful technique: (1) General septic peritonitis. (2) Intestinal obstruction due to kinking of the recently separated intestine, or to adventitious bands. This is a possibility after any serious abdominal operation, and the author has related elsewhere a case of strangulation of the lower part of the ileum by such a band successfully treated by abdominal section. Three years previously the woman had been operated on for an ovarian tumor. (3) Retroperitoneal abscess. (4) Fecal fistula occurred in one of his forty-two cases, and healed spontaneously. The enterolith may be a cause, when not escaping with the discharges. (5) Multiple abscess of the liver. (6) Gangrene of the cæcum. (7) Phlebitis of the femoral vein. (8) Communication of the abscess with the rectum, vagina, or bladder. (9) Ventral hernia, which is said to be an exceedingly frequent sequel in America. (10) Fatal hemorrhage. Bryant mentions one case from ulceration of the deep circumflex artery; Fowler another from ulceration of the iliac vein. (11) Parotiditis. Paget saw five cases following peritonitis. (12) Empyema. (13) Pericarditis.

THE TREATMENT OF GONORRHEA, ESPECIALLY WITH ARGONIN AND PROTARGOL.

Niebergall (Deutsche Militärärztliche Zeit- schrift, No. 6, 1898; Centralblatt für Chirurgie, No. 36, 1898) found that the duration of treatment with the albuminous compounds of silver known as argonin and protargol was not materially shortened. About ten days was required for the destruction of the gonococci, and ten days more for allaying of inflammation when cases came early with involvement only of the anterior urethra:
when the entire urethra was inflamed the treatment lasted much longer.

Because of the expensiveness of these products the author rejects them for use in the army; a twenty-day treatment for each individual will cost about $1.25. Thus 7000 cases, the constant average of the German army, would in a year's time cause over $100,000 to be expended on the silver salt.

He holds that irrigations with permanganate of potassium are as efficient and possess the merit of being extremely cheap.

FORCIBLE STRAIGHTENING OF SPINAL CURVATURES.

RIDLON (Medical News, Oct. 15, 1898) has attempted the operation of forcible straightening in sixteen cases of spondylitis, seven cases of scoliosis, and one case of rachitic curvature. The cases of scoliosis present nothing of sufficient interest to warrant detailed description. The youngest patient was nine years old and the oldest eighteen years; the shortest duration of deformity was eighteen months and the longest seven years. In all the cases the deformity was reduced one-third to one-half.

The patient in whom rachitic curvature was present was a male, seventeen years old, and the deformity dated from infancy. There had been no increase of deformity for fourteen years. The operation was performed on January 13, 1898, and nothing was gained in the way of correcting the deformity.

Taking into consideration all the cases of spondylitis, four patients had demonstrable abscesses, one had old sinus, and one had paraplegia. No harm appears to have arisen from the abscess complication, or from the presence of old sinus. The paraplegia appears to have been positively benefited. Two patients stopped breathing on being turned from the prone to the supine posture during the chloroform narcosis, but both began to breathe again after a short interval; in one instance the plaster-jacket was cut open and allowed to gape one inch, and in the other it was not. Only one patient showed any elevation of temperature after the operation. In this instance disseminated pulmonary tuberculosis was suspected, but not proven. The patient's temperature was not taken before the operation, and consequently it is not certain that the elevation was due to the operation. In two instances it was not possible to straighten with what seemed to the operator a safe amount of force. Pressure sores under the plaster dressings have been frequent. Their locations have been over the kyphosis, the scapular spines, the posterior iliac spines, and the sternum, and in various places about the head.

Relapsed deformity can usually be greatly reduced by a bearable amount of horizontal traction with backward bending over a footrest without anesthetization. Only two patients have as yet been allowed to get up and walk around, one in a plaster-jacket, and one in an anteroposterior leverage spine brace. In no case as yet does the author think he has obtained reliable bony solidification at the point of the disease.

All the cases of scoliosis were materially straightened and made taller, but all have lost part of the gain since the operation. It appears doubtful if a permanent straightening is maintained unless a reliable fixation-dressing is worn for a long time. Despite his failure above recorded, Ridlon is convinced that straightening of rachitic curvatures can be effected in younger patients.

THE TREATMENT OF SWEATING FEET.

GERDECK (Centralblatt für die Gesammte Therapie, October, 1898, recommends for the cure of this affection painting the soles of the feet with formalin. In the afternoon, the evening, and on the following morning the soles and heels are treated, the brush being carried over these surfaces four times; twice over the plantar surface of the toes. About twenty drops of formalin is used for each application. Four to six drops of the antiseptic is poured into each shoe.

Almost immediately the offensive odor disappears.

If a thirty-per-cent solution of formalin is used, six or seven coats should be applied at each treatment.

The effect of these paintings lasts three or four weeks, when they must be repeated. The application is slightly painful, but not in the least crippling.

INSTILLATIONS OF PROTARGOL IN CHRONIC URETHRITIS.

DESNOS (Annales des Maladies des Organes Génito-urinaires, No. 7, 1898; Monatshfte für Praktische Dermatologie, Bd. xxvii, No. 8) treats chronic diarrhea by instilling daily, or if the reaction from this is too great, every second day, twenty to sixty drops of a five-
to ten-per-cent solution of protargol into both the posterior and anterior urethras. Thirty-seven out of forty-six cases thus treated were definitely cured.

Tuberculous disease was not influenced by this treatment.

Four cases of blennorrhagic cystitis were cured by from five to seven instillations of a five-per-cent solution. When the bladder is inflamed, however, it must be entirely free of urine before the protargol is instilled.

---

**CLINICAL INVESTIGATIONS CONCERNING MUSCULAR RHEUMATISM.**

**EBEN (Centralblatt für Chirurgie, Sept. 10, 1898)** contributes a paper of great importance to surgeons as showing the danger incident to the too common diagnosis of obscure pain as muscular rheumatism.

In twelve cases of alleged rheumatic wryneck he discovered that not one was really due to rheumatism. The abnormal position was not caused by pathological contraction of the sternocleidomastoid, but was primary and was assumed to lessen pain; the muscle contracture was secondary and due to position. The pain and tenderness were in all cases on the convex side and not closely related to the muscles. Tenderness was especially elicited over the fourth upper spinous processes. In three instances the great occipital nerve was tender on pressure. In one case the smaller posterior superior nerve was tender over the mastoid process. In every instance the lateral flexion of the rigidly held head could be increased without pain. Sometimes rotation towards both sides was possible, often turning towards the convex side was difficult. None of the muscles of the concave side showed increased tonus. Pain was not caused by visible extension of the neck, hence spasm was not the cause of the torticollis. It was evident that the joints on the convex side of the cervical spine were diseased, or that the roots of the nerves passing out at this side were affected. This diagnosis was not nullified by the possibility of rotation, since this motion takes place almost between the atlas and axis.

Two hundred cases of lumbago were observed. In not one was muscular disease noted. In 119 cases there was affection of the articulations of the lumbar vertebrae characterized by tenderness to pressure over the joints, limitation of lateral flexion and lateral curvature, the concavity of this curvature being toward the sound side. Twenty-one cases were instances of neuralgia of the cutaneous nerves which have their origin in the three lower lumbar branches. The region of the vertebral articulations was not tender. In some cases the diagnosis could not be formulated. Some were alcoholics, some were beginning tabetics, and one was suffering from osteomalacia.

This study is extremely important, since it shows how often the surgeon is led to an erroneous treatment by the very common diagnosis of all obscure back pain as rheumatic; though a more accurate knowledge as to the true cause of this pain may not lead to the finding of any specific remedies for it, it will at least prevent the needless saturation of the systems of patients with antirheumatic medications.

---

**OPERATION ON UTERINE CANCER.**

**GALVORN (Centralblatt für Gynäkologie, No. 35, 1898)** operated on thirty-nine cases of uterine cancer with a hot iron. In nearly all of these the disease had extended widely; seven died shortly after operation; three in the course of six months without local recurrence. Of the twenty-seven cases reported as cured, seven were well for more than two years after operation, seven more than one year, four for more than seven months, and ten for less than six months.

---

**PYEMIC SINUS THROMBOSIS.**

**WHITNEY (Archives of Otology, February, 1898)** writes an interesting résumé, based upon three successful operative cases. Chronic suppuration of the ear is responsible for the greatest number of intracranial inflammations. Authorities have found that micrococci and bacilli were always associated in fetid secretions, while in the non-fetid only micrococi were present. Poliver determined “by culture and inoculation that the bacilli present in foul discharges were not pathogenic, but possessed saprophytic properties only, while inoculation with the micrococi produces speedily fatal sepsis.” Gruber states that this conclusion demonstrates that the offensiveness of a discharge from the ear is no criterion of the danger to be apprehended from it. The healthy mucoperiosteum offers a strong resistance against the invasion of bacterial products, and consequently absorption is very slow, the microorganisms being destroyed by the phagocytic properties of the leucocytes. When the disease becomes
chronic the tissue defense becomes greatly weakened.

The author recognizes two varieties of sinus thrombosis, viz., primary or marasmic, and secondary or infective. The last named is the usual form following middle-ear suppuration. The "path of infection" in septic brain diseases is most commonly from direct extension from diseased bone lying in contact with the skull contents.

In a thrombosed sinus "disintegration of the clot may be sufficiently extensive to cause a partial restoration of the lumen of the vessel, and the current be reestablished either through the center of the thrombus, or between it and the nasal wall, in which manner portions of the septic material are swept into the circulation and deposited elsewhere, giving rise to metastatic abscesses characteristic of pyemia." Furthermore, general infection may result from lymphatic absorption of the pyogenic organisms which penetrate the walls of the diseased veins and sinus and infiltrate the adjacent tissues.

"An attack of sinus phlebitis is usually ushered in by pain over the affected side of the head, malaise, nausea, preceded or followed by a sudden chill and a sudden and pronounced rise in temperature, 106° F. being frequently observed."

Rigors are a characteristic symptom. Vertigo is more constant when associated with meningitis; it is not a distinguishing symptom. Consciousness is a very varying symptom. In the early septic stage, Griesinger's symptom, edema of the region of the occipital vein, with marked tenderness on pressure in the upper portion of the post-cervical triangle, is a valuable guide. Edema of the eyelids of the affected side at times assists in arriving at a prompt diagnosis.

Zanzal (1886) first suggested the feasibility of opening and cleansing the sinus from purulent thrombi, and of ligating the internal jugular as a prophylactic measure.

As to the time to operate, Körner says: "As soon as you have made the diagnosis of sinus thrombosis, the moment to operate has arrived." The author believes that the tendency of infective thrombosis is always toward disintegration and the establishment of metastatic embolic processes. He further recommends that operators should always ligate the internal jugular vein when the sinus contains purulent material or a disintegrated clot. If the clot extends into the jugular vein, the vessel should be tied at the lowermost portion of the obstructed vein and as high up as possible, and then resected. In this method we avoid the probable infection from decomposition of the clot.

In cases where we cannot reestablish the circulation from below the jugular bulb, whether the disintegrated clot has been removed or not, the author states that it is an imperative duty to ligate the jugular vein.

It is very gratifying to observe that he also enters a vigorous protest against the danger of manipulating a diseased vein in the neck in the hope of dislodging the clot. This procedure is more apt to favor the further spread of the infectious material.

At the present time the prevailing opinion of operators is to tie the jugular in all cases where toxic symptoms are pronounced, or where metastases are already present. The jugular vein should be tied before the sinus is opened. Voss recommends that the sinus should first be uncovered and the diagnosis verified, after which the jugular can be ligated.

The author summarizes as follows:

First.—The indications for jugular ligation in thrombosis of the sigmoid sinus, before exposing the sinus, are:

(a) The existence of chronic otorrhea.

(b) Pronounced manifestations of pyospticemia, high fever, sudden remissions, and repeated rigors.

(c) Metastases.

(d) Griesinger's symptom, occipital edema.

(e) Edema of eyelids of corresponding side.

(f) Tenderness along the course of the jugular in the neck, and perhaps the cord-like feeling of the infected vein.

(g) Beginning neuro-retinitis.

Second.—The indications for ligation after exposing the sinus and recognizing the thrombosis, but before opening it:

(a) The presence of a clot extending well down into the bulb and disintegrated in its lower portion (as indicated by aspirator), associated with distinct pyemic symptoms, although metastases are absent.

(b) The display by the sinus of respiratory movements would render probable the admission of aerial embolism to the heart unless the vein were first tied; such movement in the sinus wall indicates the presence of a clot somewhat back toward the torcular from the point where the aspiration takes place, and has been noted by Jansen, Schwartz, and Körner, while sudden and fatal asphyxia from aerial embolism of sinus has been reported by Kuhn.
Third.—Indications for ligation after exposing and opening of the sinus:

(a) The presence of a large thrombus, extending down into the bulb, and having undergone purulent liquefaction in the deep bulbous portion, which may not have been diagnosed until the sinus was extensively opened; the curetting deeply into the neck under such conditions is fraught with imminent risk to the patient unless the vein is tied.

(b) Inability to reestablish the circulation from below, whether the clot has or has not been disintegrated, and whether or not there has been tenderness in the neck.

(c) Inability to reestablish the circulation from either direction has aroused some discussion as to the advisability of ligating both jugulars, but the author does not find that any serious consideration has been devoted to this question.

Whitney believes that it is a dangerous practice to place the nozzle of the syringe in the divided end of the jugular, near the bulb, and wash out the contents forcibly upwards and out of the opening in the sinus wall; for if the visceral layer of the wall is softened the injected fluid may rupture it and pass into the subdural or subarachnoid space, thus distributing infective material.—The Laryngoscope, September, 1898.

THE TREATMENT OF FRACTURED BONES BY OPERATION.

Barker (The Lancet, Aug. 20, 1898) states that the question as to the propriety of treating fractures by surgical operations by wiring is one which at the present time is engaging a good deal of attention. As yet the majority of surgeons appear to be agreed that for most ordinary fractures other and simple mechanical modes of treatment are quite adequate and involve less risk, and with this view the author entirely agrees. There are, however, a considerable number of fractures which proverbially give but indifferent results if treated by mechanical appliances, and to these surgeons are beginning to apply operative treatment in ever-increasing numbers. To this class belong fractures of the patella and of the olecranon, whether recent or old, and fractures of the long bones of the leg or arm in which union is long delayed or totally absent. Hitherto the great bugbear in the operative treatment of such fractures has been the risk to limb or life involved in the operation. The nature of these risks we all know, and in the past they have very properly checked and limited operative undertakings. But how far this ought to be the case now with our greatly improved technique is a matter which appears to him to be open to discussion. With a view to clear his own impressions upon this subject he has for some time past been collecting those cases in which he has operated for fractured bones and studying the results in order to see whether the series appears to justify such interference or not. As these results will probably interest others who are speculating on the same subject, the author has decided to publish them. The cases have all been operated on for injury of bones recent and old. If they have any value it lies in the fact that they form an unbroken series and have been operated on by the same surgeon, with almost identical precautions in each case against surgical accident. There are forty-six cases in all, including some in which bones have been divided for various reasons and subsequently sutured, such as, for instance, where the patella or olecranon has been sawn across to explore a joint or reduce a dislocation, but not including excisions. Of the latter it may be said that though their fate would materially and favorably influence the question of the unjustifiability of interfering extensively with bones, they belong to a somewhat different category. Of all his excisions of the knee the author has lost none, and only two have subsequently required amputation—the case of an old woman whose knee he tried to save and a young woman who came to him for amputation but whose leg he tried to save first by excision. The forty-six cases alluded to arrange themselves thus: subcutaneous suture of patella for fracture, 19; suture of patella (open method), 10; suture of olecranon for fracture, 6; suture of olecranon for dislocation, 2; suture of bones of forearm (ununited fracture), 2; suture of bones of leg (ununited fracture), 4; suture of clavicle (ununited fracture), 1; suture of patella after division, 2; total, 46.

Of the first group it need only be said that all have recovered well from the operation without any accident. The writer has made every effort to follow these cases up to date, and results have been excellent. In some few a little limitation of movement has remained, but the limb has been firm, and as far as could be made out the union of the fragments was osseous. In none so far has the wire appeared to give any trouble. Of
several he possesses skiagrams. These show that though the union is bony the adjustment of the fragments to one another was not always symmetrical. This has not appeared to unfavorably influence the movements of the joints, as we know, indeed, little irregularities in the patella in rheumatoid arthritis do not always do. Several of the patients were absolutely restored to as good use of the injured limb as though it had not been damaged at any time. Those cases in which stiffness was noticed to any extent were past middle life, and it was seen even in cases which had healed without reaction. On the whole, he is very well satisfied with his subcutaneous method of suture for recent cases at any age. For fractures which have remained unsettled for months of course the open method will be required, but such cases will become rarer and rarer as the simplicity and freedom from risk of the subcutaneous method is more fully recognized.

Of old fractures of the patella there are ten cases, and of these eight healed by first intention without any suppuration. Cases 2 and 7 suppurred, but not very seriously. The first was one of the writer's earlier cases treated long ago, and the suppuration was in the periarticular structures. He saw the patient years later with an excellent movable knee, and removed the knot of wire, which was giving him some trouble. Case 7 was one of comminuted fracture of the patella, almost compound, with loose fragments which had to be removed. Those which remained were surrounded with a "purse-string" suture and thus drawn together. Some swelling followed and effusion into the tissues above the knee, but though he made incisions only serum escaped. The main cavity of the joint appeared to be quiet all the time, though the suture wound opened and the wire had to be removed in part. Barker put this case down as suppuration, as there certainly appeared to be some, and the wound yielded pus, though not to a large extent. He has lately seen the patient, who is well satisfied with the result. There is much stiffness in the knee, though he thinks this will pass off to a great extent in time.

One of the last cases operated on was particularly interesting; it was one of transverse fracture by very slight muscular action. But the joint was enormously swollen and looked as if about to suppurate. The author opened the joint by a curved incision with the convexity upwards and found a great deal of broken-down blood-clot, almost purulent. This was removed and the bone fragments brought together with one silver wire. The wound healed absolutely by first intention and the patient left the hospital. Before he went he was discovered to have ataxic symptoms. Two months later he was admitted to the medical wards as a case of Charcot's knee, the joint having become greatly distended. As there appeared to be pus in it, it was opened by a colleague during the writer's absence and much broken-down purulent material was evacuated. It was then found that the wire had worked through the lower fragment and was loose. It was removed and the joint was drained. The man soon left the hospital healed, but with all the signs of ataxia, and has not since been seen. Had the condition which probably favored the fracture been recognized at the outset he should not have been operated upon. But the man was young and the symptoms were not well marked.

In all the eight cases where there was no trace of inflammation after the operation the results were admirable, and in the other two the state of the patients or their joints did not appear to be critical at any time.

Six recent fractures of the olecranon were wired, and with the exception of one, which was compound and comminuted, the results as to movement were admirable. All healed per primam, even the compound case, but here there remained great stiffness. The woman was fifty-three years of age, and when the adhesions were broken down under an anesthetic about a month after discharge from hospital the line of union—in the fragments gave way in spite of the "purse-string" silk suture. In the other cases the results were almost or absolutely perfect.

Recently Barker saw a blacksmith's hammerman whose broken olecranon he wired two and a half years ago, with as strong and movable an arm as if it had never been broken. The method employed for some years has been to make an oval flap, drill the fragments transversely, and use wire, making the knob on the outside. In only one case so far has the wire given trouble. It irritated the skin and had to be removed. In two cases he divided the olecranon as a preliminary to reducing old dislocations of the elbow. In one, a boy aged twelve years, though firm union resulted, there was considerable stiffness of the joint when he left the hospital. He has not been seen since. In another, a woman aged fifty-six, whose dislocation dated from four months back,
he divided the olecranon, reduced the dislocation, and primary union resulted. When last heard of the result bade fair to be perfect. In two cases the radius was cut down upon and wired for old-ununited fracture. The first he has not seen since the operation; the last, a middle-aged woman, recovered with primary union and with good use of her arm. The clavicle united perfectly under one dressing and all the symptoms were relieved.

In two cases the author divided the patella for access to the joint and wired at once. The union was primary in both without reaction and the patients left, much relieved in one case; the other was a private case and was quite relieved.

Of the four cases in which the bones of the leg were wired for ununited fracture primary union took place in all, and the functional result was perfect in three. But in the first union had not taken place in the bones when last seen and the patient cannot be traced.

The writer states that he thinks the results encouraging, especially as they were achieved in an old hospital now happily being rapidly rebuilt. With care and experience the results ought to be better in the future.

THE CONSERVATIVE AGENCY OF SHOCK.

Dr. H. G. Wetherill (Journal of the American Medical Association, March 12, 1898) in an article on this subject deduces the following conclusions: (1) Surgical shock entirely unassociated with hemorrhage is a condition rarely seen, and one which may usually be successfully treated in persons who are otherwise in good health. (2) Hemorrhage, though small in amount, is a far more important factor in the production of surgical shock (as it is seen clinically) than we have been accustomed to think it. (3) This mixed shock (traumatic asthenia) should be designated by some distinctive title, or the term shock be construed to comprehend all the factors in its genesis. (4) While not proven, it seems probable that the effect of even a small continuous arterial hemorrhage is to produce through its reflex action lower blood-pressure, and in general a condition so like true shock as to be very difficult of differentiation, particularly if the hemorrhage is concealed, as in ruptured ectopic pregnancy. (5) Surgical shock, with or without hemorrhage, must be construed as primarily conservative in its tendencies. The incident prevention of rapid exhaustion, of acute suffering, or great blood loss when the blood-vessels are opened, all tend to the ultimate saving of life. (6) Premature stimulation in the treatment of traumatic asthenia may defeat this conservative effort of Nature. Bleeding should be stopped and proper provision made for the comfort and welfare of the patient before strong stimulation is resorted to, unless there is imminent danger of death. (7) Anesthetics must be sparingly and carefully given to patients suffering from surgical shock (traumatic asthenia), chiefly because they completely obliterate the reflexes. The saturation of the patient with an anesthetic may turn the scale against him, even though the direct effect of the anesthetic be stimulant. The same rule holds good in regard to the employment of alcoholic stimulants if too freely used. (8) We should cooperate with and supplement Nature's conservative efforts. They are always exercised in behalf of the patient, never against him.

TWO CASES OF RECOVERY FROM TRAUMATIC TETANUS AFTER THE USE OF ANTITOXIN.

G. G. Davis (Annals of Surgery, August, 1898) reports two cases of traumatic tetanus successfully treated by tetanus antitoxin. The author had formed the opinion that the value of antitoxin in the treatment of tetanus was not proven, encouraged thereto by a contribution of Dennis. Davis pushed its administration, both as to the amount and length of time, to the extent of his resources. His first case developed stiffness of the muscles of the back one week after the wound, and four days later this had involved the neck and jaws. He reported for treatment one week from the first appearance of his symptoms. At that time the pulse was below 100, respiration 36, and there was stiffness of the muscles of the back, most marked in the lumbar region. In the following twenty-four hours there was no marked progression of symptoms. The antitoxin was then administered. The case in all received forty-two doses of eight to ten cubic centimeters in eighteen days.

The second case developed tetanus two weeks after the wound and was given twenty-eight doses of the antitoxin (Roux) in twelve days. Sedative drugs were used in addition to the antitoxin.

The first case was comparatively mild; the second case when he came to the hospital
was having three to eight spasms per hour, and had been suffering from symptoms for a week prior to presenting himself. Both these cases recovered, and the reporter has the impression that the antitoxin did help them. It is worthy of note that over a hundred dollars' worth of the antitoxin was used.

UREMIA IN THE PROCESS OF CHILDBEARING.

In the American Journal of Obstetrics for August, 1898, Lewis writes on this subject. He says that prophylaxis is of the utmost importance in the treatment of the uremia of pregnancy, since by proper dietary very many cases of severe intoxication may be nipped in the bud. The occurrence of albuminuria or other symptom of faulty elimination, such as low specific gravity, small daily amount of urine, headache, nausea, etc., should be the signal to put the patient at once on a milk diet, exclusively milk for a while, until the cessation of the alarming symptoms indicates more latitude in the menu. The diet throughout the rest of the pregnancy should contain little of the red meats or other food likely to cause an excess of the nitrogenous contents of the blood. The pregnant woman with albuminuria should not travel, for fear of the excitation of the genital organs produced by the jarring of the train. Iron and other tonics should be used for the anemia which is often present. Mild diuretics and drinking of much water should be advised. Warm baths or Turkish baths are useful and not at all dangerous unless in excess. Laxatives, preferably the milder salines, should be given as often as needed to keep the bowels free.

Should the prophylaxis fail there comes up the question of interference with the pregnancy. If, in spite of proper effort and of proper cooperation on the part of the patient, the symptoms should continue to become more grave, especially should the daily amount of urine continue to diminish and the total urea to remain low, he thinks the weight of present authoritative opinion would advise induction of labor. As in the incoercible vomiting of pregnancy, each case must be duly considered by itself as to when the time for interference has come. Of course the method employed to induce labor will depend upon the time of the pregnancy. As the very first labor pains are likely to excite convulsions, it is imperative to be as quick as possible. Manual dilatation, Barnes' bags, instrumental dilatation, Tarnier's escateur, or the deep cervical incisions of Dührsen, will be used according to the circumstances of the individual case. Charpentier and the French as a rule advise waiting for the natural supervision of labor and ending it naturally if possible. They entirely discard forced labor and Caesarian section in eclampsia, preferring the use of chloral to the point of narcosis. Dührsen and many of the Germans advise immediate and even forcible delivery in eclampsia or when that is imminent, always under deep chloroform anesthesia. Between these comes the great body of the profession, which adopts a middle course within these wide limits.

The fact that, in eclampsia continuing after the labor, there seems to be a decided benefit observable from free hemorrhage points to the rationality of blood-letting at any time when spasms occur. This procedure seems more beneficial in those acute cases accompanied by much edema, large amount of albumen, sudden onset of the uremic symptoms, full, bounding pulse, and cyanosis. Bleeding seems rational in such an array of conditions if ever, whatever the cause of the convulsions may be, whether uremia, heat-stroke, epilepsy, or what not. Without doubt it has almost always, under such circumstances, been immediately beneficial in puerperal uremia, but there is question whether it does not do more ultimate harm than good. The relief may be immediate; but as the volume of blood returns to normal by the inhibition of water from the alimentary canal and the tissues, or from hypodermoclysis, the tension returns, and we are then confronted by the former conditions with the addition of an acute anemia. According to Leyden's idea, the very lesion in the kidney is anemic. Therefore, while it may be justifiable in the plethoric to do phlebotomy in order to gain time for the action of eliminative drugs and for obstetric interference, yet the procedure is dangerous and should not be carried to any great length. Venesection was the treatment in Guy's Hospital before 1868, and the mortality in puerperal eclampsia was thirty per cent. Since then it is 20½ per cent under the treatment by chloroform.

Since the overwhelming weight of opinion is that the eclampsia is caused by faulty elimination, and since the vast majority of authorities recommend measures directed to favoring elimination by the skin, bowels, and kidneys in the early stages of the intoxication, it would seem to follow that radical
means ought to be employed in that direction when the graver attacks come on. Such is the justification for the use of pilocarpine, hot air, elaterium, and the drastic hydragogues. One should remember in employing these measures that they all tend to weaken the heart, and that upon the maintenance of the cardiac strength depends our hope of recovery. They should be used only with caution and in cases where the pulse is of good quality, unless they be used as forlorn hopes after other measures have failed.

Veratrum viride has been used, especially in this country, since its introduction by Fearn, of Brooklyn, in 1869, in cases of uremic attacks of all kinds, and it has vigorous partisans in the convulsions of child-bearing. Jewett refers to twenty-two cases, in only one of which did convulsions recur after treatment had been established. He advises its use subcutaneously in doses of ten to twenty minims until the pulse-rate has been brought under 60, when, in his experience, spasms will not occur. Similar good results have not been obtained in England from veratrum. In American literature there are very many favorable reports of cases, but nobody has, as far as the author knows, published a series of cases, covering any length of time, giving both sides of the statistics of the use of veratrum. Many who recommend veratrum advise and use also rapid evacuation of the uterus under chloroform anesthesia. In an affection where so much depends upon maintaining the force and regularity of the heart, it seems very heroic and dangerous treatment to employ to its toxic action so powerful a cardiac depressant as veratrum, with the aim of controlling the spasms, which are themselves only a symptom of serious poisoning of the blood and of a vicious nerve state kept up by the presence of the contents of the gravid uterus. It would require very encouraging statistics indeed to induce the writer to trust alone to any method which avowedly only controls the visible explosions of the disease, to the exclusion of measures calculated to eliminate the poison, if possible, and to terminate as soon as safely can be the condition of pregnancy, which is at the bottom of the whole trouble.

In 1887 Gustav Veit strongly recommended morphine in large doses for puerperal eclampsia. He begins with a dose of half a grain, and follows it soon with a smaller dose, unless the narcosis is complete. He gives another dose as soon as consciousness begins to reappear, and keeps the patient in that condition for hours, or even days, until the child is born and the tendency to spasm ceases. No other treatment is recommended. Olsenhagen favors the morphine treatment, but would permit forceps or version in the interest of the child, if these operations could be easily performed. The action of the narcosis paralyzes the voluntary muscles and thus stops the attacks, which in themselves tend to increase the arterial pressure and consequently the morbid condition in the kidneys and in the brain. The prognosis for both mother and child is said by the advocates of this treatment to be better than by any other method. Löhlein claimed that it had reduced the maternal mortality to fourteen per cent, and that the infant mortality had been reduced to forty-one per cent. Dührssen criticizes Löhlein’s statistics, both as to their accuracy and on the ground that they embrace too few cases to be of value. In the latter’s collection of 325 cases of eclampsia from all German clinics were eighty-six cases where the morphine treatment had been used, not, however, by any means to the exclusion of other measures. In these eighty-six cases, twelve or fourteen per cent died, excluding complicated cases. The general mortality of the whole was nineteen per cent. Some difference of opinion will always exist as to what cases, in a series given to prove percentages, ought to be excluded on account of complications.

The advocates of prompt obstetric interference in cases of the graver uremic manifestations in pregnancy base their claims upon various considerations. In the first place it is known that in the vast majority of cases the spasms cease or grow less severe as soon as the child is born, therefore the sooner that is brought about the better for the patient. The chief reason for not inducing labor is that the manipulations to that end will of themselves precipitate convulsions. This is not the case if the patient is under complete narcosis. Therefore, if narcosis be complete and the operation be done quickly, the patient is soon brought out of the condition of intoxication and of spasm and stands a better chance of recovery than if allowed to remain therein while the convulsive phenomena are palliated by cardiac depressants or by prolonged dosing with large amounts of morphine. The great trouble, especially in young primiparæ, who are the most subject to these attacks, is that it is very difficult to artificially empty the uterus with despatch. The earlier the eclamptic
seizures begin the harder to induce the labor. The accouchement force is apt to be dangerous of itself. Dührssen devised an operation to overcome this difficulty. In the primipara, after the head has become engaged in the pelvis toward the last few weeks of pregnancy, the body of the cervix becomes effaced, and though the os may be as tight as a pin-hole, yet the cervix is stretched over the protruding head in a thin layer. The main time in inducing labor is taken up by the dilatation of the os. Dührssen makes incisions laterally, and, if necessary, anteriorly and posteriorly, completely to the vaginal attachment through the cervical tissue, thus entirely and at once obliterating the period of dilatation of the os. Then he turns or applies high forceps and delivers at once, perhaps doing episiotomy if there is difficulty in passing the head over the perineum. He claims that the incisions thus made usually heal without incident or can be repaired like ordinary lacerations. The patient is thus at once brought into the puerperium, and, if the eclampsia continues, the other means mentioned may be used against it with the very favorable circumstance that now the pressure of the distended uterus is eliminated from the causation. In a symposium at the Boston Obstetrical Society these conclusions were reached: that nothing is gained by delay in puerperal eclampsia, that the continuous administration of anesthetics has not been known to allow of the reappearance of the convulsions, and that slow manual dilatation and emptying of the uterus has been repeatedly successful. Dührssen’s method now makes this slow manual dilatation unnecessary. In multiparae the internal os is usually not open, nor is the cervix flattened out over the head, so that in such cases manual or instrumental dilatation must be employed instead of the deep cervical incisions. Where immediate delivery in eclampsia is imperative, even Cæsarian section has been strongly recommended. Puech considers that in a pregnant woman, if the albuminuria persists in spite of milk diet, and especially if it be accompanied by gastrointestinal symptoms and dyspnea, the maternal interests demand the induction of labor. Indeed, modern opinion seems to be tending toward ending the pregnancy as soon as it is evident that the uremic symptoms are not being controlled by the dietetic and diuretic treatment, and not to wait until the graver accidents, such as coma or eclampsia, come upon us unawares.

Reviews.

The author of this book, Dr. Stöhr, is professor of anatomy in the University of Würzburg, the translator is the director of histology in the Woman’s Medical College of Pennsylvania, and the editor is demonstrator of this branch in the Harvard Medical School at Boston. To some of our readers the first American edition of this volume is probably already familiar. To the present volume the editor has added a number of illustrations taken from original drawings; new editorial remarks and criticisms of the text have also been introduced.

Of the numerous books on histology which have recently appeared this strikes us as being one of the best, not only because of its contents, but because of the beautiful way in which it is printed, with large type on heavy paper, the wide pages making a book which lies readily open on the desk before the student and is easily perused. As a matter of fact, if we were called upon to choose between this book and that of Dr. Dunham, which we reviewed in our last issue, we would find it difficult to make a decision. It is interesting to note in this connection that this volume is recommended by the professor of pathology and histology in the Jefferson Medical College to the students of that institution in the teaching of histology.

It is very proper that the professor of obstetrics in such an important school as the University of Pennsylvania should come before the profession and students as the author of a complete and accurate text-book of obstetrics; and a close examination of the pages of this volume reveals two facts, namely, that they bear almost invariably the personal opinions of the author neatly associated with the opinions of others. This is evidenced not only by the text, which shows a wide knowledge of obstetrical literature, but by the copious foot notes which can be turned to by those who desire to look into the matter under discussion more fully. This volume, although it covers over 800 pages, may be considered a most concise work, and
while it is too bulky to be readily used as a handbook, it is of such size that it contains all necessary obstetric knowledge without becoming so unwieldy as to be burdensome. In many of the foot-notes the author expresses views which he does not think it wise to express in the body of the text. The illustrations are many of them original, and the original ones are as a rule the most valuable. We are interested to note that Dr. Hirst condemns, as we believe all good obstetricians and therapists condemn, the use of pilocarpine in eclampsia. His treatment consists in the use of hot packs, hypodermoclysis, or intravenous injection, and the administration of full doses of the extract of veratum viride. In the treatment of postpartum hemorrhage it is advised that the fluid extract of ergot be given hypodermically into the thigh, but we do not believe that this preparation is suitable for this purpose, first, because it is not absolutely reliable so far as its effect upon bleeding is concerned, and secondly, it is apt to clog the syringe and produce an abscess. The “aseptic ergot” is much to be preferred for these reasons and purposes. The only part of the book which seems to us to need revision is the index, for which the author is not directly responsible, for in it typographical errors are not rare and cross-references are lacking. Nevertheless, the index is adequate and only needs slight correction to be as good as the text.

While there are already a number of recent and very excellent books on obstetrics which can be used by students, this one seems to us to give promise of being exceedingly popular with the class of persons for whom it was written, and Dr. Hirst has produced a volume of which he himself, his friends and his pupils will be proud, and one which the profession in general will find most valuable as a practical guide.

This is a small octavo volume of about 700 pages, including the index. Why the fourth American edition should be published upon the basis of the second English edition when the third English edition appeared this fall and is in accord with the new English Pharmacopoeia we do not know, and for this reason that part of the text which has been written by Dr. White does not represent his latest views upon therapeutics.

Dr. W. Hale White is well known to the profession in general by reason of his very able and interesting investigations which have been made at various times concerning fever and a number of other clinical conditions which have an important bearing upon the practice of medicine. Dr. White is also the lecturer on therapeutics at Guy’s Hospital, London, and some of our readers are probably aware that his book on General Therapeutics, which deals with remedial measures other than drugs, is an ably written and interesting volume.

The present edition, from the point of view of the English text, represents a concise statement of modern therapeutics, and the American editor has added a very large amount of matter with the idea of making it represent the views of American physicians as well. These additions upon the part of Dr. Wilcox are useful and reflect the opinions of his American brethren. Sometimes they are absolutely antagonistic to the views of the author. Thus, Dr. White evidently does
not believe that phosphorus is of any value in rickets, whereas Dr. Wilcox expresses a diametrically opposite opinion. The book from its size lies between a compend and a more exhaustive book upon therapeutics, and deals with therapeutics in a manner which makes it better adapted for first and second year students than for those who are further advanced in their medical course. The fact that this is the fourth American edition proves that its value is appreciated, and we doubt not that it will continue to be used by the class of pupils that we have named with advantage and a gain in knowledge.

This little compend has within a few years reached its sixth edition. Owing to the death of its well known author some years ago it became necessary for the publishers to obtain the aid of a physician who was capable of keeping it up to the most recent advances in obstetrics, and Dr. Wells has succeeded in the task which has been set him. Like most of the books in this series, it is published in the question and answer form and will doubtless remain in the future as in the past a popular compend for those who wish to "cram" this branch before going up for examination. We doubt whether the statement made on page 33 in regard to ovulation has been proved correct, namely, that frequent coitus results in frequent ovulation.

This is a book of less than 200 pages devoted to the Brand method of treating typhoid fever and written by one who has perhaps had a larger experience with this method than almost any other living physician. It is based, we are told, upon an experience of a consecutive series of 1902 cases treated at the Brisbane Hospital, and is copiously illustrated, in order to show the methods which the author has employed in the technique of the bath, and as to the means by which the patients are to be transferred from the bed to the bath and from the bath to the bed. Dr. Hare's method is one which is designed to conserve to the utmost the strength of the patient and to prevent him from using any effort on his own part during the bath. It is also designed to make the patient as comfortable as possible during the bath, a factor of great importance, for oftentimes the posture of the patient in the water is exceedingly uncomfortable, and it requires considerable muscular effort to prevent his head from being submerged.

We notice in reading this essay that, like many other clinicians who think for themselves, Dr. Hare has not blindly followed the arbitrary dictates of those who insist upon every detail of the bath being carried out in every case. It is evident that he recognizes the fact that individuals differ in the treatments which they require, and we believe that a part of his good results is due to the recognition of this fact. The bath treatment was, however, employed by him in all his patients after a certain date, with the exception of those who refused to submit to it, cases in which the temperature failed to attain the bathing point, which is 102.5°, and, most important, cases in which contraindications were present. It is needless to say that the comparisons made by Dr. Hare of the results of the cold-bath treatment, as compared to those of the so-called expectant method before he introduced the bath, are very favorable to hydrotherapy. Aside from the modifications of the treatment which we have mentioned and which make its use more agreeable to every one concerned, the author states that allowance must be made for the fact that as Brisbane is practically in a tropical climate patients naturally object less to the bath than those living in a colder zone. He also emphasizes the fact so greatly emphasized by Brand, that the bath must be used by the fifth day if the best results are to be obtained, and that it cannot be used late in the disease as a rule. This is an important point, overlooked by some and contradicted by others of less experience. Again, owing to the high temperature of the atmosphere in Brisbane baths were almost always given at a temperature of 75° or 80° instead of below this point, and therefore the shock to the patient was not as great as if colder water had been used. An important omission was made in that frictions were not made because the wards were "short-handed," but some of the disadvantage in this respect was more than counterbalanced by the fact that the patients were not exposed to very cold water.

Dr. Hare frankly points out that the treatment does not shorten the disease. Thus in 373 cases treated by the expectant method the fever lasted twenty-four days, and in 966 cases by the bath method it lasted 23.3 days.
So far as the stay in the hospital is concerned, which is, of course, a mirror to a certain extent of the time required for convalescence, we learn that the stay in the hospital in 431 expectant cases was 35.9 days, and in 1033 baths 31.6; in other words, but four days were saved in convalescence, and the fever was not shortened. Concerning relapses, 46 took place after normal temperature in 999 cases which were bathed, and 64 relapses took place if those cases are included in which the relapse came on when the temperature had not fallen to normal but was as low as 90°. The mortality of the relapse cases was 8.7 in the 46 cases named, or 12.6 in the 64 cases named. It is therefore evident that the bath increases the tendency to relapse, and that in the relapse mortality is greater than it is in primary attacks.

In regard to perforation and hemorrhage we find that before the bath was used there were 4.70 per cent of cases of death from this cause in 576 patients, and that after the bath was instituted there were 4.1 per cent of deaths from these causes in 1902 cases.

This monograph is an exceedingly valuable one to those who are interested in the discussion of this very vital question—and who is not? Dr. Hare has been unusually careful in the comparison of his statistics. Curiously enough, however, he has made one very important omission. Thus in studying the possibilities of error in his calculations he ignores the most important point in the whole field, namely, the differences in mortality which occur in the disease at the different periods at which it comes under treatment by the Brand method. Proper nursing, sanitary care, and slight medication, with the use of proper forms of hydrotherapy to control the fever, instituted as early as the fifth day in all cases of typhoid fever, would give a very low death-rate, whereas similar treatment or the bath treatment instituted later in the disease would permit a higher mortality. Further, if the bath were universally employed in late cases it would probably increase the mortality if the teachings of Baruch, H. A. Hare and others are correct, namely, that in the late stages of typhoid, when the body is too feeble to react, the baths are capable of doing harm.

In the treatment of typhoid perforation F. E. Hare believes in immediate operation as soon as enough morphea has been given to abate the violence of the pain, but first to wash out the stomach if vomiting has begun. When a perforation is found he thinks it ought to be enlarged longitudinally and the bowel drained, thoroughly closing the opening afterwards by a double row of Lembert sutures. The physician should examine the lower portion of the bowel to see that no secondary perforation is present, and if any spot seems about to perforate it should be treated as if it had perforated. After this the peritoneal cavity should be thoroughly flushed with warm water and a glass drainage tube inserted. He believes that the best incision is the slightly curved one recommended for operations in appendicitis. He thinks that the alteration in the rate and character of the pulse after perforation is sufficient to separate this condition from almost all forms of violent pain which come on in the abdomen during typhoid fever.

Dr. Gould has come to be known by the medical profession as Facete princeps a builder of good medical dictionaries, for both of his larger volumes have been universally recognized as exceedingly valuable contributions to lexicography. The present pocket manual is smaller than the average visiting list, and therefore can be readily carried in the pocket.

It is needless to state that it is correct so far as it goes, but its very abbreviated form necessitates equally abbreviated definitions. We happen to notice that the definition of paracresol, while correct, does not convey to the student the idea that paracresol is used in medicine as an antiseptic and disinfectant.

This is but an illustration of the necessity of abbreviation. Naturally, also, this small volume does not contain all the useful tables which characterize Dr. Gould's larger publications, but a number of them, as, for example, the table of the muscles and of the nerves, are introduced.

Dr. Purdy's book upon urinalysis and urinary diagnosis is probably the most popular work that has ever been published on this subject, for three large editions of it have been exhausted in three years, and we are told in the preface that upward of sixty medical colleges have adopted it for a text-book. It is an octavo volume of 350
pages, well printed and well illustrated, and
deals chiefly with the clinical side of the
study of the urine. Because of the con-
cise way in which the facts are stated, and
because useless material has been excluded,
it is exactly what it professes to be, a com-
plete and yet condensed summary of the
subject, and we congratulate the author
upon having been able to present a book
upon a well worn theme which has attained
such an extraordinary success, a success
which it is needless to say it well deserves.

Diet and Food Considered in Relation to
Strength and Power. By Alexander Haig, M.A.,
M.D., F.R.C.P. Illustrated.
ton, Son & Co. 1898.

We have received a copy of this little
brochure of eighty-three pages from both
the English and American publishers. Dr.
Haig is well known for his interesting studies
upon uric acid as a factor in disease, and
while many of us are unable to agree with
him that it is as much a factor as he would
have us believe, he deserves an immense
amount of credit for having called atten-
tion to a very important part of medical
study. As may be gathered from the title
of this book, it is a short essay designed to
illustrate the necessity of regulating the
quantity of the various foods which are
taken in daily life, so that they will best
supply the demand of the body under varying
circumstances, and this subject of course
cannot fail to be of interest to every one,
whether he be a layman or a medical man.
The book is well worth the half-hour's pe-
rusal which is required to grasp the points
which Dr. Haig presents.

A Manual of the Practice of Medicine. By Fred-
erick K. Taylor, M.D., F.R.C.P.
ton, Son & Co. 1898.

This small octavo volume, amounting to
over a thousand pages, is familiar to many
practitioners on both sides of the Atlantic,
and has been fortunate enough to reach its
fifth edition in the short space of eight years,
proving that Dr. Taylor's experience as a
teacher, physician, and examiner has qualifi-
ced him to prepare for his professional col-
leagues the information which they find use-
ful. The present edition has been reset in
type and is somewhat larger than its prede-
cessors. New chapters have been introduced
concerning glandular fever, angioneurotic
edema, and similar comparatively rare ma-
aladies. A separate section is devoted to Dis-
eases of the Mediastinum. The author tells
us that he has obtained much valuable infor-
mation from the "Twentieth Century Prac-
tice of Medicine," from Allbutt's "System
of Medicine," from Manson's "Tropical Dis-
eses," and from Cole's "Treatise on the
Blood."

While there is nothing distinctly original in
the character of this book, it is a condensed
and valuable summary of medicine. In some
portions of the book the paragraphs devoted
to treatment are not as complete as might be
desired, and the author does not state his
own opinions in a sufficiently dogmatic way.
The book can be most cordially recom-
meded to both students and practitioners
as being a little less bulky than most of the
volumes which are well known which deal
with practice, and yet not so condensed as
some of the small manuals which are forced
to leave out important material.

A Primer of Psychology and Mental Disease.
For Use in Training Schools for Attendants and
Nurses and in Medical Classes. By C. B. Burr, M.D.

Dr. Burr has prepared this second edition
of his small octavo volume upon insanity and
psychology within a comparatively short time
after the appearance of the first edition. It
is really a "primer," as its name indicates,
and does not attempt to deal with the deeper
problems which would naturally be consid-
ered in a larger volume. Indeed, it is a book
more suitable for nurses than for physicians.
An interesting glossary of neurological terms
opens the volume.

Manual of the Diseases of the Skin. By L. Dun-
can Bulkley, A.M., M.D. Fourth Edition, Revised
and Enlarged.

It is undoubtedly because this book is
truly a manual and deals in such a thoro-
guously practical way with the diagnosis and
treatment of skin diseases that it is already
in its fourth edition.

The first few chapters are devoted to the
general considerations of the study of derma-
tology, anatomy and physiology of the skin,
symptomatology, etiology, and classification.
This latter is particularly simple and easy to
bear in mind.

In the sixth chapter there is an analysis of
twenty thousand cases of diseases of the skin,
showing the relative frequency of the various
disorders. It is worthy of note that acne,
cezema, psoriasis, and syphilis hold first
rank.

There are at the end of the book 118
prescriptions representing those found most
useful in dermatology. There is, moreover, an accurate medical index.

This is certainly a book which is likely to be most useful to the general practitioner. The author has carefully avoided vagueness in either symptomatology or treatment, and has stated briefly and clearly the results of his own exceptionally large experience.

Yellow Fever in the West Indies. By Izett Anderson, M.D.

This is a small octavo volume of about one hundred pages, dealing with the author's experience in the treatment of yellow fever during a period of thirty-four years in the West Indies. Having been forced to retire from practice, he has now gathered together his notes and case-books, and has written the pages of this volume from the information derived therefrom. His object in writing the volume has been to help younger practitioners who settle in the West Indies to practice, as he believes that a clear conception of the etiology, pathology and treatment of this disease will aid them very materially in their work.

The second edition of Hayden's book has been enlarged by a chapter upon the Care and Use of Urethral Instruments; also it has been more profusely illustrated. In other respects the text is much the same as that of former editions, excepting that it has closely followed new and excellent modern teachings and is perhaps more systematic in arrangement and more clear and direct in its diction than before. This is saying a great deal, since the work admirably covers the diagnosis and therapeutics of gonorrhea, chancreoid, and syphilis. It is a thoroughly trustworthy guide, and as such is worthy of the warmest commendation.

Brief Essays in Orthopedic Surgery. By Newton M. Shaffer, M.D.

From the title of this work a surgeon would not unnaturally expect a brochure which would represent practically an epitome of orthopedic surgery. In this he would be disappointed, since the book contains a number of essays dealing with the ethics of the specialty rather than with the details of practical treatment. None the less, it is admirable and instructive reading.

The views of the distinguished author upon orthopedic surgery as a specialty are well expressed in the following sentences: "Before it can be a real specialty it must cease to appear in the rôle of a competitor with general surgery. It must not 'overlap.' Its disciples must cease to antagonize the best elements of the profession by posing as orthopedists, when they only lack opportunity to become general surgeons. And until this change is brought about there will be no true orthopedic surgery, except as here and there a man stands up for the right and defies criticism, for it is getting to be almost as rare to find a legitimate orthopedic surgeon as it is to meet with an orthodox gynecologist who does not 'overlap' and compete with the general surgeon in operating for appendicitis, etc."

Cleft Palate; Treatment of Simple Fractures by Operation; Diseases of Joints; Antrectomy; Hernia, Etc. By W. Arbuthnot Lane, M.S.

Lane, who is well and favorably known to the American profession as an ingenious and skilful surgeon, has collected in book form a number of his clinical lectures. These deal with cleft palate, acquired deformities, mechanical or traumatic arthritis, some clinical observations on the principles involved in the surgery of fractures, treatment of simple fractures by operation, some of the consequences of wearing boots, tubercular affection of joints, some experiences in the surgical out-patient room of a children's hospital, treatment of inguinal hernia, a consideration of the principles that should guide us in the treatment of abnormal mechanical conditions of the hip-joint, antrectomy as a treatment for chronic purulent otitis media.

The field covered is a wide one, but the treatment of the various affections is practical, and even the experienced surgeon will find much that is helpful in this little book.

Correspondence.

London Letter.

In the Journal of Laryngology Dr. Eugene Yonge reviews the treatment of dyspepsia in laryngeal tuberculosis by drugs and by other methods. In selecting a drug the question to be solved in the bulk of cases is, what local anesthetic, while sufficiently powerful, is also prolonged in action, devoid of marked
poisonous effects, and not specially disagreeable to taste? Dr. Yonge carefully experimented with fifteen local anesthetics, both to ascertain their relative efficacy in relieving pain and also to decide their special fitness for this particular purpose. Like many other physicians, Dr. Yonge is driven to the melancholy conclusion that no drug is ideal for all cases, but that there are several which may be selected in any individual case, viz., cocaine, antipyrin, eucaine, orthoform, carabolic acid, guaiacol, ice, morphine (with or without iodoform), and paramonochlorphenol. He discards as useless holocaine, aneron, aconite, and tropacocaine. When ulceration is present any of the above drugs may be tried, but when there is no lesion of the mucosa, only cocaine, antipyrin, eucaine, carabolic acid, and ice are available. When perichondritis is present, antipyrin appears to be preferable to cocaine because its effects are more prolonged, and the amount necessary to produce analgesia is free from all risk. When cocaine has to be used for a long time, it is best mixed with either carabolic acid or antipyrin, which increases its influence without increase of its substance. Similarly iced solutions of five-per-cent cocaine were quite twice as active as the same strength of solution at the temperature of the air. With extensive ulceration a combination of morphine and iodoform could be relied upon to provide some measure of relief for several hours. Orthoform similarly produced its effects speedily and lasted for some hours, and the complete absence of any toxicity even in comparatively large doses makes it in many cases superior to cocaine. Guaiacol with or without menthol exercises some sedative and antiseptic influence on mild degrees of ulceration. Eucaine is in all ways less active than cocaine, and should be reserved for those cases in which there is any special idiosyncrasy to contraindicate cocaine. Solutions of paramonochlorphenol in glycerin were decidedly anesthetic after producing a preliminary period of rather severe smarting.

Of methods other than drugs, Dr. Yonge prefers rectal feeding, in severe dysphagia, to the esophageal tube, the passage of which is most distressing to the patient and may serve to increase the extent of the local mischief. He has nothing to say of such surgical procedures as curettement, arytenoidotomy, or epiglotpectomy, because he has not yet encountered a case of severe dysphagia which, while uncontrollable by drugs, was such as to justify surgical interference by reason of the state of the lungs and the general condition of the patient.

At the Manchester Therapeutical Society Dr. Wild read a paper on the toxic effects of boric acid. He referred specially to two cases in which this very innocuous drug produced dermatitis and other irritative effects, administered in small doses of ten to fifteen grains over a considerable period of time. Dr. Wild detailed some experiments by which he sought to show the rate of elimination of boric acid in the urine. In the presence of kidney disease toxic symptoms were not unlikely to result from accumulation of the drug in the system. He expressed the opinion that the addition of boric acid in small quantity to food as a preservative was harmless, but exceedingly liable to cause mischief in the larger quantities in which it is sometimes employed.

We most of us regard our overcoats with the reverence they deserve for warding off many evils from our frail selves, but alas! we have nursed a snake on our bosoms. After the recent snow-storm in Birmingham a large number of the men employed in clearing the streets were supplied with overcoats by the Birmingham County Council. The drenching rain saturated the overcoats so that they dripped about the men’s hands and knees. Large areas of sloughing skin surrounded by a zone of inflammation and edema testify to the severity of the baptism. In some of the cases the nearest lymphatic glands are acutely enlarged and painful. The medical officer of health reports that the overcoats are replete with chloride of zinc, which is used abundantly in their manufacture. The Birmingham County Council have got the snow-drifts off their hands, but in their stead they have sixty injured employees and 300 death-traps of overcoats.

The Medical Society of London at its last meeting discussed the value of pressure in the treatment of wounds. An interesting discussion took place, and the balance of opinion seemed decidedly against pressure. The advocates of pressure employ it to secure apposition of the edges of wounds, to prevent oozing, to prevent bagging of fluid, to restrain muscular action, to prevent the yielding of cicatrices, and last but not least, to keep the dressings in place. Pressure firm enough to bring the edges of a wound otherwise apart into apposition was not unlikely to provoke sloughing and other evils, in Mr. Pearce Gould’s opinion. The use of the drainage tube had rendered it
a quite unnecessary procedure in dealing with pent-up secretions; and, indeed, pressure was more likely to produce than to prevent serous exudations, because it could not influence the arterial circulation, and pressure on veins would certainly tend to this end. Pressure could not conceivably prevent the accumulation of blood in the abdominal veins. Mr. Doran was of opinion that pressure was useful after abdominal operations, because it assisted the patient to pass flatus, which was a cardinal point in the after-treatment of these cases. But Pearce Gould in questioning this special advantage aptly remarked that when a person is suffering from indigestion and flatulence, he does not button his trousers tightly up, but on the contrary makes everything loose.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

My readers have undoubtedly heard about Dr. Tuffier, professor agréé at the Faculty of Medicine and surgeon of the Paris hospitals, and Dr. Doyen, of Reims, former house surgeon in Labbé’s service, who is well known for his success in gynæological operations. There has been some trouble between them, and recently Dr. Doyen wrote an open letter to Dr. Tuffier, which he sent to various medical men in Paris. In it he accuses Dr. Tuffier of having taken the principal ideas carried out in a recent instrument invented by him and used them for his own instrument, which shows only slight modifications from the general plan of Dr. Doyen’s invention.

This instrument was called a vasotribe by Dr. Doyen when he first brought it out, and he used it to crush the tissues surrounding the utero-ovarian and uterine arteries, so as to produce compression without ligature or use of artery forceps. In fact, it is a modified artery forceps, with very large jaws and a special groove, all of which was calculated with the greatest care by Dr. Doyen. Dr. Tuffier borrowed the general form of Doyen’s instrument, added a new method of bringing the branches together—not so good perhaps as that of Doyen’s, and resembling somewhat the basiotribe of Tarnier—and called the instrument by a new name, angiotribe. When Dr. Tuffier presented his invention to the Society of Surgery, he failed to mention Dr. Doyen’s name in a sufficient manner, hence this letter.

Dr. Doyen not only upbraids Dr. Tuffier with withholding his name in this communication, but also accuses him in veiled terms of distorting his statistics by important omissions. Dr. Tuffier, it seems, though rather taken aback, is now preparing his answer. All this is a part of a sort of secret rivalry that exists between the surgeons of the Paris hospitals and the younger school of surgeons that has established itself in the provinces and will not bow down and worship the authority of the Paris confrères. It is in reality a form of the tendency to decentralization which has begun to show itself, and of which one manifestation consists in the creation of regional universities.

An excellent method indicated by Dr. Humm, of Brunswick, in cases of neuralgia of the head or cephalalgia, consists in the use of pulverizations of ether on the affected spot. These pulverizations, which can be carried out with an ordinary spray, should be kept up until the skin is covered with a white deposit. Sometimes a single pulverization is sufficient; in other cases two or three applications are necessary. These applications do not in the slightest degree hurt the skin.

Dr. Winkler, of Vienna, has come to the conclusion by his researches on the influence of amyl nitrite on animals that this agent when used pure is more harmful than when it is saturated with a gas such as oxide of carbon. By using the drug in this latter condition he did not notice any dyspnea or pulmonary edema such as is observed in some cases when the drug is employed pure. On trying it on himself he saw that there was dilatation of the smaller arteries, as indicated by congestion of the face, but he did not have that disagreeable sensation of fulness in the head such as is felt in most cases. He concludes that the drug well saturated would be advantageously used.

A new treatment of tetanus has been advised by Baccelli, and consists of subcutaneous injections of a solution of carbolic acid. An observation is furnished by Dr. Ziego, in which the injections were begun eight days after the appearance of the first symptoms in a man having a complicated fracture of the forearm. A three-per-cent solution in distilled water was used, and as there were no signs of intolerance the dose was raised from thirty to fifty centigrammes. No symptoms of poisoning were noticed with the exception of a slight degree of albuminuria. In all there was injected 978 centigrammes of car-
bolic acid in twenty-seven days, and, as Baccelli recommends, morphine (four to six centigrammes) was given at first. The third day of treatment there was a slight amelioration, and nine days later the trismus had disappeared. Complete recovery seems to have been obtained on the twenty-third day. This is the thirty-second case of tetanus treated by Baccelli's method, and there has been so far only one death, which is certainly very encouraging, as the ordinary mortality of tetanus is seventy per cent. Moreover, though a few cases have been cured by Dr. Roux's and Borrel's treatment, a fresh series of cases terminated fatally; but this treatment seems to have been applied in desperate cases, therefore it is readily understood why the results are not more favorable.

The use of gelatin as a coagulant not only in wounds, surgical or accidental, but also as a means of producing coagulation in aneurisms, has given rise to much discussion as to its real action and its efficacy. Some authors have doubted whether gelatin, when absorbed by the cellular tissue, remains what it is at first, and whether its original properties can be relied on. Two fatal cases during the use of gelatin in aneurisms have seemed to throw some discredit on this new method, but then it has not been clearly shown that death resulted from anomalous coagulation. One thing is sure: coagulation by this method depends on the spontaneous coefficient of coagulation of the blood, and it would seem to be necessary to determine this approximately before using this method. On the other hand, death may supervene during this treatment without being due to the treatment. Dr. Fernet had a case of aneurism in his service and was on the point of applying this new method. The patient died the day before, and if he had been injected the very same day grave doubts might have arisen as to the safety of this treatment.

Mr. Carnot, house physician of the hospitals, has published a long article in the Presse Médicale, where he indicates in what cases his method may be used. Without being able to more than briefly outline his article, we may say that he uses the method in cases of hemorrhage, according to their being aseptic or septic. In the former case his ordinary solution may be used, which is as follows:

Gelatin, 50 parts by weight;  
Chloride of calcium, 10 parts by weight;  
Distilled water, 1000 parts by weight.

In some cases a small amount of glycerin may be added, as indicated by Dr. Gueyrat. In sterilizing these solutions the temperature of 115° C. should not be surpassed, and the solution should be used only a few degrees above its liquefying point. When this solution is used in a septic cavity such as the nasal fossæ or the vagina, as it would serve as an excellent means of culture, it should be antisepticized either by the use of corrosive sublimate or a small amount of hydrochloric or hydrofluoric acid, and the tampons laden with gelatin should be left as short a time as possible in contact with septic surfaces. Mr. Carnot is much more reserved in his appreciation of the use of gelatin internally or by subcutaneous injection. He has found that the use of a solution of chloride of calcium is efficacious in the treatment of gastric ulcer, when there is much hemorrhage.

Notes and Queries.

AGAINST PATENTING ANTITOXIN.

The following preamble and resolutions offered by Dr. Arch. Dixon, of Henderson, Ky., at the recent meeting of the Mississippi Valley Medical Association, were unanimously adopted:

Whereas, The general public, the medical profession, and the drug trade of the United States have long sufferedextortion at the hands of foreign manufacturers of synthetic remedies; and

Whereas, Our lax and indulgent patent laws bestow a triple monopoly upon the process, the composition, and the name of chemical products for medicinal use, thus excluding every possibility of a healthy competition; and

Whereas, The same evil has been recently disclosed in the domain of biological medicine by the patent granted Professor Emil Behring and the Hoechst-Farberwerke on antitoxic serum, a patent which could not be obtained in Germany, France, England, or Canada; therefore

Be it Resolved, By the Mississippi Valley Medical Association, that the seal of its condemnation be placed upon the unethical and unprofessional conduct of Professor Behring; that it is the duty of every member to renounce the use of the Behring serum; and that the American manufacturers who propose contesting the patent in the courts are entitled to the moral and substantial support of every American practitioner.

Resolved, That an earnest appeal be made to the members of the commission on the revision of our patent and trade-mark laws, appointed by President McKinley, and their assistance invoked for the modification of existing laws and the suppression of prevailing abuses.

Resolved, That a copy of these resolutions be sent to every medical journal in the United States and to the members of said commission, as follows: Hon. Arthur P. Gleeley, Assistant Commissioner of Patents, Washington, D.C.; Hon. Peter Grosscup, Chicago; and Mr. Francis Forbes, New York City.

Resolved, That the members of this society be urged to write their congressional representatives at Washington and bespeak their support of any measures of relief ultimately proposed by the Commission.

PERICARDIAL EFFUSION: ITS DIAGNOSIS AND TREATMENT.

By H. A. Hare, M.D.,
Professor of Therapeutics in the Jefferson Medical College and Physician to Its Hospital.

However clearly the physical signs and symptoms of effusion into the pericardium or pleura may be described in the text-books, there probably does not exist a practitioner of experience who has not met with cases in which he felt grave doubt as to the presence of fluid. Further, there are few of large experience who have not found all the signs of pleural effusion present and then had their theoretical diagnosis brushed aside by the mortifying accident of having a “dry tap” when thoracentesis has been performed. Though the technical differences between the physical signs of pulmonary consolidation and pleural effusion, or cardiac dilatation and pericardial effusion, may be manifest in books, practical experience reveals that they are often misleading or so perverted as to be useless.

Of the question of pleural effusion nothing more need be said, but of that of pericardial effusion it is necessary to speak, first, because it probably occurs much oftener than it is diagnosed, and second, because it is
capable of jeopardizing the patient's life more speedily than a pleural effusion.

The occurrence of pericarditis is met with as a result or complication of acute rheumatism in about fifteen per cent of the cases in males and ten per cent in females. In this disease we are usually on the lookout for it, but in croupous pneumonia it is a much more frequent complication than is thought. We know that it is found in about twenty per cent of the cases which come to autopsy, and therefore it probably occurs with even greater frequency if the total number of cases is considered. It is a not infrequent complication of scarlet fever, and is met with as a result also of sepsis, tuberculosis, and even in chorea, in which disease Osler found it present in nineteen out of seventy-three autopsies. It also occurs in subacute or chronic maladies, notably in gout and Bright's disease, to such an extent that the French call it "pericardite Brighthique." When we recall the additional fact that it may occur in diabetes and as an extension process from pleuropneumonia, it is evident that it is a common condition. Of course, it is true that a very considerable portion of cases are not accompanied by effusion, but on the other hand it is the forms with effusion which are the most insidious, coming on without pain or other symptoms which would direct attention to the pericardium; and not until dyspnea, restlessness, and impaired circulation are manifested does the physician suspect pulmonary disease, or a pericardial effusion, and when he begins to diagnose its existence meets with contradictory signs and symptoms. It is true that we find as a rule distant heart sounds which are muffled and feeble, but such a condition of these sounds is met with in other states; that the apex beat is displaced, but so it is in pleural effusions and in chronic adhesive states following plastic or mediastino-pericarditis; that the area of cardiac dulness on percussion is deformed or enlarged, particularly to the right, but here again a very similar condition is met with in cardiac dilatation.

What, then, are the symptoms which may be considered pathognomonic? I doubt if there are any, and believe that we must rely upon the history of the case, the general symptoms, and the physical signs combined, plus experience.

Rothschild has claimed that dulness on percussion in the fifth right intercostal space indicates fluid in the pericardium, but I have seen cases in which no fluid was present and in which dulness existed in this area; and this has been well pointed out by Broadbent, Lees, and Ewart, who have found that the dilatation of the heart accompanying rheumatism in children often gives this sign.

When are we to be suspicious, then, of this insidious and dreaded state? In the first place it should be recalled as a possibility in all of the diseases we have named when dyspnea and respiratory, plus cardiac, distress are manifest, and the very fact that these symptoms may arise in Bright's disease as the result of uremia as well as effusion should not be overlooked.

The diagnosis should, I think, be made certain by the insertion into the fifth right intercostal space of a long fine hypodermic needle carefully sterilized and already attached to a sterile syringe, with which some suction may be made if need be. The needle should be pushed in gently and directed anteroposteriorly, and as it enters the chest the syringe should be held very lightly between the forefinger and thumb so that it is as if balanced. If by any accident the heart is punctured even by the tip of the needle, the motion of the syringe at once reveals this fact and it can be withdrawn far enough to escape the heart wall. In other words, this is a single exploratory puncture, and while it deals with a part or organ which is supposed to be vital and vulnerable to a high degree, it is I think justifiable, first, because if the patient's symptoms are pressing he is in great danger from his effusion; second, because if the fluid is withdrawn his life may be saved; and third, because notwithstanding the fear of an injury of the heart being fatal, as a matter of fact it is an organ which permits the most extraordinary pathological changes without losing its function, and receives insults better than some other organs, like the liver and kidney. As a matter of fact death after a puncture of the heart results as a rule from the same causes as death due to a stab of a large artery, namely, in the sense of great loss of blood, or more commonly by the outpouring into the pericardium of blood which, while it is not sufficient to cause death by direct loss of blood, so presses on the heart that its action is arrested. Only when the coordinating center of Kronecker is punctured does death ensue, and as this can only be found after careful search with a sharp instrument when sought for in the bared heart, and as the septum is far removed from the area suggested for puncture, this accident could scarcely occur.
Experimental evidence and records of cases can be adduced in abundance in support of these assertions, and I have recently collected some of these facts in the Therapeutic Gazette for 1898.

This exploratory puncture not only informs us of the presence of fluid, but of the position of the heart if any part is in the line of the operation. Sometimes the abstraction of small amounts of fluid will give relief, but if not, then a more competent aspirating apparatus can be used, such as is commonly employed in the operation of thoracentesis.

THE NON-OPERATIVE TREATMENT OF SUPRAPUBIC VESICAL FISTULA, ILLUSTRATED BY A CASE COMPLICATED BY A COMMUNICATING PELVIC ABSCESS.

By Charles Lester Leonard, A.M., M.D., Assistant Instructor in Clinical Surgery and Instructor in Skilagraphy, University of Pennsylvania; Surgeon to the Southern Dispensary, etc.

Surgical teachings must always be understood to include the employment of antisepic or aseptic methods. The effect of antisepsis will be noted in the difference in the results obtained in the following case:

Three months before she came under my care Mrs. G. had been operated on for a pelvic abscess. By some mischance the bladder had been opened and a suprapubic fistula had formed, through which both urine and pus were discharged, while there had been a continuous interchange of infection between the abscess, the bladder, and the surrounding pelvic cellular tissue.

The only treatment the patient had received before I saw her had apparently been based on the known tendency of such fistulae to close spontaneously, but little had been attempted in antisepsis, and as a consequence the patient grew worse. Her general condition was very poor, while the condition of the perivesicular connective tissue resulting from the protracted infection can be imagined. The profoundly depressed condition of the patient and the extent of the infection, with the probability of renal involvement, made it seem desirable to defer operation until the patient’s physical condition could be improved. She was therefore removed to a private hospital ward, where strict antisepsis could be maintained.

The first indication in the treatment was the prevention of any further interchange of infection between the bladder and abscess cavities.

Suprapubic siphon drainage was secured for the bladder in the following manner: A fine rubber drainage tube was threaded upon a silk ligature attached to an eyed probe. After the probe had been passed through the sinus into the bladder, and while it was held by the attached ligature, the drainage tube was slipped over it into the bladder. A suitably connected tube conducted the urine into a receptacle beneath the bed. Drainage tubes were passed into the abscess cavity and sinuses in a similar manner. A wall of granulation speedily formed between these various tubes and effectually prevented any further intercommunication.

The marked cystitis was treated by irrigating with hot boric acid solutions, and as soon as inflammation of the external genitalia, which had resulted from the continual flow of pus over that region, had subsided a catheter was passed and through-and-through irrigation was used daily. The urine was also sterilized and rendered acid by the administration of benzoic acid as employed by Emmet in the following formula:

重要作用: b, Acid. benzoelic, 3 ij; Acid. borici, f 3 xij; Aqua dest., f 3 xij.

Misc. Sig.: One tablespoonful well diluted three or four times daily.

The general pelvic tenderness was rapidly decreased by the external application of a fifty-per-cent ichthyol ointment and the same drug used in vaginal suppositories.

The greatest difficulty experienced was in the treatment of the abscess, as antiseptics had to be employed that would not irritate the bladder, while it was impossible to get good drainage. The complete emptying of the abscess cavity and thorough antisepsis were secured by the employment of the official boroglyceride, which while acting as a non-irritant antiseptic also acted by its greater specific gravity, causing the displacement and expulsion of all the pus.

Although the progress towards recovery was at first slow, the combined local and constitutional treatment enabled the patient to make such progress that operation was again postponed.

As soon as the urine became normal and the sinuses ceased to discharge pus, the suprapubic drainage was removed and catheterization at regular intervals substituted. The drainage tubes in the sinus leading to the abscess cavity were not removed till the
urinary fistula had healed. This occurred promptly after the removal of the siphon drainage. The sinuses leading to the abscess cavity were then allowed to heal; their healing, however, did not take place as rapidly.

In all the sinuses the first drainage tubes introduced were necessarily small, but each gradually dilated the sinuses in which it lay, when a larger one was introduced in the manner described.

The continued good health of the patient (now over two years) and the knowledge of the condition probably produced by the numerous pelvic adhesions have deterred the author from further operative interference, which unless new indications arise seems hardly justifiable.

The case is of interest as a demonstration of the relief that proper antiseptic measures can afford in cases where suppurative disease has so depressed the system and devitalized the tissues that operative interference is hazardous and inopportune. It also illustrates the fact that conservative antiseptic surgery, in certain instances, is capable of assisting Nature to accomplish cures where radical operation would certainly be attended by failure; and further, that asepsis or antisepsis is essential to the spontaneous closure of suprapubic vesical fistulae.

1930 Chestnut Street.

THE INHIBITORY INFLUENCE OF FREE OXYGEN ON THE GROWTH AND MULTIPLICATION OF TUBERCLE BACILLI; AND THE TREATMENT OF TUBERCULOSIS WITH THE SYRUP OF IRON CHLORIDE—AN EXPERIMENTAL STUDY.

By George W. Weir, M.D.,
New York.

In treating the various forms of anemia at the Bellevue Hospital Dispensary in the spring and summer of 1892 I succeeded in obtaining, in a period covering four months' time, twenty-five cases. These cases embraced: (1) simple anemia, or where both the corpuscles and hemoglobin are diminished; (2) chlorosis, or where the corpuscles are normal and the hemoglobin diminished.

The result was the usual increase of corpuscles and hemoglobin in the blood and a distinct improvement in the general health of each individual patient.

Attention is specially directed, however, to only one of the above cases, viz., a case of anemia with phthisis, in which the treatment consisted in the administration of the syrup of iron chloride in large quantities, with no other treatment except a proper consideration for the digestive tract.

The case referred to is as follows:

April 29, 1892. L. O., female; American; aged twenty; hemoglobinometer registered 32. Anemia pronounced. Sputum shows tubercle bacilli. Physical examination reveals dulness on percussion over left lobe, associated with crepitant râles, bronchial voice, and high-pitched respiration. Ordered syrup iron chloride, half an ounce three times a day.

May 13. No apparent improvement; complains of pain in chest, and slight constipation. Ordered cascara sagrada, and increased iron to one ounce three times daily.

May 18. Appearance somewhat improved, but complains of pain in the chest. Iron increased to one and one-half ounces three times a day.

June 1. Patient feels stronger; no constipation nor irritation of the stomach. Hemoglobinometer registers 48, an increase of 18 points in thirty-three days.

June 15. Hemoglobinometer registers 55; patient feels better; appetite improved. The iron was now increased to two ounces three times a day.

July 8. Appearance very much improved; complexion good. Complains of cough, which is attributed to cold contracted on rainy day. Hemoglobinometer registers 68. Iron increased to 2½ ounces three times a day.

July 20. Hemoglobinometer registers 70. Weather hot and sultry. The patient has gained in weight 7½ pounds since April 30. Sputum reveals bacilli, but scattering and diminished in number.

July 29, nine days after, I sailed for Europe and was absent for a period of six months. I have never seen the patient since.

What caused the improvement in this particular case? The woman's environment was anything but favorable, and such that hygienic measures were out of the question. Did the ingestion of the iron stimulate nutrition and assimilation, or check tissue waste or promote tissue repairs? Did the increase of the red blood-corpuscles and the hemoglobin excite intraorganic oxidation and fortify the lung tissue against the onslaught of the tubercle bacilli?

These thoughts led me to experiment to ascertain, if possible, what the action of free oxygen might be on a growing culture of tubercle bacilli in the laboratory. To this
end I had manufactured a special thermostat which presented on each side a series of tubes for the purpose of introducing and getting rid of the oxygen gas. This, with wash-bottles, and a series of test-tubes of original design, completed the outfit.

The accompanying diagram will show how the experiments were conducted.

![Diagram with labels: a.a, thermostat; b.b, oxygen gas cylinder; c.c, tubes facilitating the introduction and outlet for the oxygen; d.d, test-tubes, with culture media and growing cultures; e.e, wash-bottles outside thermostat; f.f, wash-bottle inside thermostat; G.G, sand-bath, temperature of the blood.]

These experiments came under the observation and supervision of Professor Crookshank and his able assistant, in King's College, London; Professors Prudden, Cheeseman, and Hodenpil, at the College of Physicians and Surgeons, New York; and Professors Loomis and Buxton, at Loomis' Laboratory, New York. It seems unnecessary, therefore, to make any comment on the technique employed in the experiments. Sufficient it to say that everything was done that was suggested by these eminent gentlemen to render the experiments free from error; and I take this occasion to thank them for their assistance and courtesy and painstaking efforts to render the experiments accurate.

The following is a résumé of the experiments as conducted at King's College:

**Series A.**—Five test-tubes containing nutrient media (agar-agar glycerin) inoculated with virulent tubercle bacilli November 22, 1892. A slow current of warm oxygen gas was allowed to pass over the same for a period of twenty days.

In each tube the growth of the culture was completely retarded; the consistency of the cultures appeared to be somewhat mealy, differing from normal cultures, and they did not appear to adhere to the surface of the nutrient media; the color was changed to a reddish brown. Other nutrient media inoculated with these cultures did not take. The culture under the microscope showed that the organism was not destroyed, but was found less difficult to stain.

When a slow current of warm oxygen gas is passed through a bottle containing growing tubercle bacilli for a period of three days an apparent disintegration is observed, and a white precipitate is seen at the bottom of the bottle. To ascertain whether the cultures had lost their pathogenic properties, three rabbits were inoculated; none of them showed any symptoms of tuberculosis.

Similar experiments were made at the College of Physicians and Surgeons, New York.

Five tubes containing nutrient media were inoculated with tubercle bacilli April 28, 1893, and submitted each day to a slow current of warm oxygen. The tubes were placed in the thermostat April 28, and oxygen applied May 2, four days later, for a period of twenty-four hours, and on May 5 for thirty minutes; May 6, one hour and fifteen minutes; May 8; one hour and forty-five minutes; May 9, one hour and fifteen minutes; May 11, two hours; May 12, three hours; May 13, two hours; May 17, thirty minutes; May 20, two hours; May 22, two hours; May 23, two hours; May 24, two hours; May 25, two hours. Covering a period of thirty days the tubercle bacilli we
under the influence of the gas forty-six hours and fifteen minutes, or an average of about an hour and a half each day. The appearance of the tubercle, regarding both color and consistency, was similar to the bacilli submitted to a continual current of oxygen for a period of twenty days.

The experiments seemed to show that while tubercle bacilli are aerobic, an excess of oxygen inhibits their growth and multiplication. The question arises, then, what is the exact relation of oxygen, and in what proportion to the proper nutrition and development of this organism? To what degree is an excess of the gas germicidal? To what extent does it inhibit their growth; and how much, if any, does it decrease their virulence?

The following experiments were made at the Loomis Laboratory, New York:

Nutrient media were inoculated with tubercle bacilli February 13, 1896. Oxygen (four tubes) started February 28. Common air (four tubes) started February 28. Control (three tubes), i.e., normal conditions for growth.

February 28, oxygen applied 30 minutes, common air 30 minutes; March 5, oxygen 40 minutes, common air 40 minutes; March 7, oxygen 45 minutes, common air 45 minutes; March 9, oxygen 1 hour and 15 minutes, common air 1 hour and 15 minutes; March 12, oxygen 1 hour and 15 minutes, common air 1 hour and 15 minutes; March 13, oxygen 60 minutes, common air 60 minutes; March 17, oxygen 60 minutes, common air 60 minutes; March 19, oxygen 60 minutes, common air 60 minutes; March 22, oxygen 60 minutes, common air 60 minutes; March 25, oxygen 1 hour 30 minutes, common air 1 hour 30 minutes; March 28, oxygen 60 minutes, common air 60 minutes. Total, 64 days in thermostat; subjected to influence of oxygen gas 34 days 695 minutes, or daily average of about 20 minutes.

Admitting that free oxygen and ozone destroy the tubercle, what practical value have the experiments in connection with the treatment and cure of the terrible disease—tuberculosis? With our present knowledge of the disease, probably no value whatever.

One of the most prominent specialists of lung diseases in New York, Dr. Chas. E. Quimby, recently made a statement to the effect that he seldom came across a patient suffering with the disease who was not susceptible to improvement. Dr. Quimby divides tuberculosis into two conditions: (1) tubercle; (2) the septic condition.

The tubercle, or rather the millions of tubercle bacilli which cause the destruction of lung tissue, and the septic condition are so securely encased in healthy tissue as to be apparently protected from the influence of any germicidal agent. In fact, the opinion has been expressed by one authority that if the blood could be impregnated with an antiseptic up to nearly the point of corpuscular ruin it would probably flow through the lungs without causing the death of one bacillus.

The “second condition” of the disease would appear, then, to be the only condition that admits of any rational treatment.

The ingestion of iron oftentimes increases the desire for food and the ability to dispose of it, and serves as a permanent tonic. In the case which I have mentioned the patient gained 7½ pounds in weight and 28 points in hemoglobin from April 29 to July 20, or a period of eighty-two days. The corpuscles in this case were not counted, but it is fair to presume their number was largely increased. The quantity of iron the patient was taking when she paid her last visit was 2½ ounces three times a day, or 250 minims of the tincture of the chloride of iron of the U. S. Pharmacopoeia.

There are so many preparations of iron on the market that it is difficult to say which one possesses the greatest merit. The preparation mentioned, viz., the syrup of iron chloride, is the old-fashioned tincture of the iron chloride slightly modified, each ounce of which contains forty minims. It is easily borne by weak stomachs and can be taken in large quantities without deranging the digestive tract—a great advantage over many other preparations. The form of iron that is to be employed, however, to improve nutrition, increase the hemoglobin and the red corpuscles, must be left of course to the judgment of the attending physician.

---

**REPORT OF 78 CASES OF PULMONARY TUBERCULOSIS TREATED AT THE WINYAH SANITARIUM, AT ASHEVILLE, N. C., IN 1898, WITH WATERY EXTRACT OF TUBERCLE BACILLI.**

**BY KARL VON RUCK, M.D.**

In making the following report I wish in the first place to disclaim any possible impression that the results recorded are attributed by me entirely to the specific remedy

---

*Syrup iron chloride, Parke, Davis & Co.*
employed, inasmuch as I appear to have been misunderstood by some authors, who in referring to my previous report of 182 cases, suggested that the favorable climate of Asheville, and other advantages which my patients were afforded, have no doubt also had their equal influence in obtaining my results.

Had my reviewers read my report carefully, they would have found the following sentence immediately below the summary of the results: "This report is, however, not made with a view of convincing my hearers of the great value of one particular remedy employed, and I am fully aware that a variety of favorable influences has contributed to these results."

I am in exactly the same position at this time, having never been willing to do anything but the best that I felt capable of in the management and treatment of my patients, and in the treatment of the present series the climatic treatment, the dietetic, hygienic and hydroopathic measures, the institution management and control of the patients, the use of the pneumatic cabinet, of inhalations and symptomatic medicinal treatment, were all deemed essential and were employed as required, while the specific medication was administered.

If, however, we wish to show the influence of the specific remedy (in the present instance of the Watery Extract of Tubercle Bacilli) we can perhaps do this with sufficient accuracy for all practical purposes by examining the results obtained in this and in other institutions, without the use of specific germ products, and which show apparent recoveries in from ten to twenty per cent only; the difference in the percentage depending no doubt upon the stages in which the cases came under treatment, and also upon the fact that many patients leave off their efforts to get well, when they are only more or less improved, hoping that no further relapse will thereafter occur.

Many such unfinished cases necessarily enter into reports from institutions, and in all my series, with and without specific treatment, still better results would, no doubt, have been shown, had the improved and greatly improved cases remained long enough under treatment to accomplish the best attainable results.

The evolution of specific medication for infectious diseases has made enough progress, at this time, to justify the serious and thought-ful attention of medical men, and supplies a most interesting and gratifying chapter in the history of medicine of the closing century.

In tuberculosis this is only less apparent to those who lose sight of the limitations that all remedies must have in their power of removing pathological processes, which frequently attain a degree from which recovery or even improvement is absolutely impossible.

The pathological changes of tubercle are no exception to this general truth, as we recognize it, for instance, in syphilis, where stages are often reached in which specific medication is absolutely useless.

During the life of the patient it may be difficult and at times impossible to determine the exact pathological changes present, and so it comes that in practical medicine we often attempt the accomplishment of that which a full knowledge of the true pathology in the particular case would show us to be useless.

The use of bacterial products as specific remedies for tuberculosis had its origin with Koch’s Tuberculin in 1890, and all the modifications which have since been brought forward were derived from the fluid upon which the specific germs had been grown.

It was believed that in this fluid certain proteid substances resulting from the tubercle bacilli, either as secretions or excretions, or both, were accumulated, and that the peculiar influence of this fluid depended upon these accumulated proteids.

In the meanwhile it was suggested that the tubercle bacilli must necessarily contain this principle within their bodies, but all efforts for its extraction proved signal failures.

To test this assumption, dead tubercle bacilli were used in animal experiments, but the regular formation of abscess at the point of injection, and the occasional occurrence of spurious tubercles in the body of the experiment animal, showed plainly that this method of treatment could not be made use of in the human subject, though the animal experiments gave indication that the germs did contain the curative substances desired.

In the further efforts to obtain this curative substance directly from the tubercle bacilli, various methods were resorted to, especially by Professor Koch, who, in April, 1897, announced his "Tuberculin R," with which he believed the desired object had been attained.

This product, however, has since been found to be an emulsion of fragments and

*Therapeutic Gazette, May, 1896.
of whole tubercle bacilli, which, when the remedy is filtered through porcelain, remain upon the filter; and it has been further shown that with this residue virulent infection can be produced.

The fact that the curative substances could not pass through a porcelain filter was acknowledged by Koch in his paper, and should have been sufficient to establish that a true solution of the germs was not present. The subsequent withdrawal of "Tuberculin R" by the manufacturers was undoubtedly on this account.

In my own efforts to obtain the desired solution, I succeeded, in February, 1896, by the method heretofore published,* and which I may again describe for the benefit of those to whom my previous publication is not accessible:

"The tubercle bacilli are filtered out of the rapidly growing and highly virulent culture. After washing with distilled water for the removal of the remains of the culture fluid, they are dried in a vacuum desiccator. Next they are powdered in an agate mortar and then extracted with sulphuric ether. This extraction removes the fats. They are again dried and powdered as before, and their further extraction takes place in sterilized distilled water over a warm bath with a temperature of 130° F. The proteids becoming dissolved in the distilled water, the fluid is then decanted and filtered through porcelain, when finally the amount of proteids is determined and the preparation standardized to a certain per cent."

Reasoning backward, and recognizing that all the various tuberculin preparations have shown a certain degree of clinical value, it seems quite probable that proteids of tubercle bacilli entered into all of them during the growth of the culture, and also into some of them during the process of manufacture.

The amount of proteids was undoubtedly small and variable, and was associated with the organic substances from the culture fluid.

The Watery Extract as produced by me, and into which absolutely no culture fluid enters, is free from organic substance and other impurities. It is a perfectly pure solution of the germs only, and being filtered through porcelain is absolutely free from any germs or fragments thereof.

For its preservation a fraction of a per cent of phenol is added, which in no wise alters its clinical value.

For convenience of administration and to avoid mistakes in making dilutions, we prepare three different strengths of the solution: No. 1 (white label) contains \(\frac{1}{5}\) of one per cent of the solid extract, free from water; No. 10 (yellow label) contains one-tenth of one per cent; and No. 100 (red label) contains one per cent of the extract.

The treatment of cases is begun with No. 1 (white label), and the initial dose is one-tenth of one cubic centimeter, or \(\frac{1}{10}\) of a milligramme of the anhydrous extract. From this dose we increase daily by one-tenth of a cubic centimeter, so that on the second day we give two-tenths cubic centimeter, the third day three-tenths, the fourth day four-tenths, and the fifth day five-tenths of one cubic centimeter. The latter dose equals \(\frac{1}{40}\) of a milligramme of extract.

I usually repeat five-tenths of a cubic centimeter of No. 1 several times, and then I again increase by tenths, until the daily dose is one cubic centimeter. From now on it is more convenient to use solution No. 10 (yellow label), one-tenth of a cubic centimeter being equal to one cubic centimeter of No. 1.

Repeating each dose once or twice we increase by tenths or twentieths of a cubic centimeter until half of a cubic centimeter of No. 10 is given as the daily dose. I find that this dose is quite active—i.e., it shows an unmistakable influence over tubercular processes—therefore the further increase can be more gradual, and as the doses become still larger the intervals between the injections are first increased to thirty-six hours and later to forty-eight hours.

The further increase of one-tenth cubic centimeter every second dose can be made with the same solution, or we can now use solution No. 100 (red label), of which one-tenth cubic centimeter is equal to one cubic centimeter of No. 10, or to ten cubic centimeters of No. 1.

It is, of course, a matter of choice with those who wish to use this preparation to make their own dilutions, either from No. 10 or No. 100, but as the doses are increased the solutions No. 10 and No. 100 are desirable, to obviate the necessity of bulky injections.

Koch, presuming that he had a true solution, stated at the close of his paper that it was the end of possible improvement of specific remedies for tuberculosis and that nothing better could be produced. However this may be, I can confirm his successful animal

*THE THERAPEUTIC GAZETTE, June, 1897.
experiments alike by the use of "Tuberculin R" and by the use of my Watery Extract of Tubercle Bacilli, in the actual cure of guineapigs, as well as in the obtaining of a considerable degree of immunity; that is to say, animals protected with the Watery Extract of Tubercle Bacilli and with like doses of Koch's "Tuberculin R" proved refractory to virulent infection, while the control animals developed the disease and died.

In the same paper in which Professor Koch announced his new tuberculin, he also gave the suggestion of producing a serum of possible value by immunization of animals with that preparation.

This was undertaken in my laboratory immediately, and on the 3d of May, 1897, the immunization of four goats was commenced. The immunization was continued in two of the animals until October, and in the remaining two until November. Two animals received Koch's "Tuberculin R," from one to seventy cubic centimeters daily, and two received like doses of my Watery Extract of Tubercle Bacilli for the same length of time.

With the serum, taken at different stages of immunization from these animals and at various periods after the supposed immunization was completed, we endeavored to protect guinea-pigs against infection, and to treat them after infection. In the method for protection we followed that of Fisch, who in October, 1897, claimed satisfactory results from his serum made by using "Tuberculin R." All these animals developed and eventually died of tuberculosis, and no appreciable result was obtained in immunization or treatment.

My results being so strikingly at variance with those of Dr. Fisch, though carried out with the greatest of care, I repeated the experiments; this time, however, with the serum made by Dr. Fisch himself, and purchased from his laboratory.

On April 5, 1898, the method of protective treatment as published by Dr. Fisch was begun with animals Nos. 305, 306, 307, 308, 309, 310, and 311, and continued for one month, when they were all infected by implantation of tissue from a fresh tubercular spleen. In addition, we infected for control animals Nos. 312, 313, 314, and 315.

The injections of Fisch's serum were continued in Nos. 309, 310, and 311, all with the following results:

Animal No. 305, protected with Fisch's serum: Original weight 765 grammes, at death 512 grammes; died August 22. Post-mortem showed point of infection a caseous mass, with perforated skin; glands enlarged, mostly caseous; spleen and liver enlarged, full of small tubercles; few tubercles in lungs; extensive pneumatic consolidation. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 307, protected with Fisch's serum: Original weight 490 grammes, at death 405 grammes; killed September 16. Post-mortem: point of infection a caseous mass, ulcerated; glands enlarged, many caseous and soft; liver, spleen, and lungs full of tubercles, some of them caseous. Microscopical: many tubercle bacilli in all the tissues examined.

Animal No. 308, protected with Fisch's serum: Original weight 500 grammes, at death 440 grammes; killed September 16. Post-mortem: point of infection caseous; glands enlarged, some caseous and soft, others fibroid; liver and spleen enlarged, and contained caseous and fibroid tubercles; adrenals tubercular. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 309, protected with Fisch's serum and subsequently treated with the same in doses of 0.3 to 0.5 cubic centimeter every other day until death: Original weight 516 grammes, at death 410 grammes; killed September 16. Post-mortem: point of infection, caseous mass and open ulcer; few tubercles in peritoneum; liver and spleen greatly enlarged and full of tubercles; many tubercles in lungs. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 310, protected and treated same as No. 309: Original weight 470 grammes, at death 440 grammes; killed September 16. Post-mortem: point of infection, fibroid tubercle; glands enlarged, few caseous, most of them fibroid; liver and spleen greatly enlarged, full of miliary tubercles; lungs tubercular. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 311, protected and treated same as Nos. 309 and 310: Original weight 500 grammes, at death 430 grammes; killed September 16. Post-mortem: point of infection, caseous ulcer; glands enlarged, fibroid
and caseous; liver and spleen enlarged, full of tubercles; lungs slightly tubercular, several caseous masses. Microscopical: many tubercle bacilli in all tissues examined.

Animal No. 312, control, infected (but not protected or treated): Original weight 520 grammes, at death 460 grammes; killed September 15. Post-mortem: point of infection caseous; few tubercles in peritoneal adhesions; glands enlarged, many of them caseous; liver and spleen enlarged, and contained many miliary tubercles; few isolated tubercles in lungs. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 313, control: Original weight 620 grammes, at death 580 grammes; killed September 15. Post-mortem: point of infection caseous, surrounded by recent tubercles; most glands fibroid; liver and spleen greatly enlarged, full of miliary and a few caseous tubercles; numerous tubercles in lungs; adrenals enlarged, tubercular. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 314, control: Original weight 570 grammes, at death 550 grammes; killed September 15. Post-mortem: point of infection, hard indurated mass; glands enlarged, most of them fibroid; few caseous; liver and spleen enlarged, full of tubercles; lung, few fibroid nodules. Microscopical: tubercle bacilli in all tissues examined.

Animal No. 315, control: Original weight 510 grammes, at death 460 grammes; killed September 15. Post-mortem: point of infection, caseous mass; glands enlarged, some hard, some caseous and soft; liver, few small tubercles; spleen enlarged, and contained many miliary tubercles; lungs, few fibroid tubercles; adrenals enlarged, caseous. Microscopical: tubercle bacilli found in all tissues examined.

Animal No. 316, control: Original weight 470 grammes, at death 420 grammes; killed September 15. Post-mortem: point of infection caseous; glands enlarged and hard; liver greatly enlarged, and contained large caseous tubercles; spleen enlarged, many small tubercles; lungs, few caseous tubercles. Microscopical: tubercle bacilli in all tissues examined.

These results are entirely in conformity with those from the use of my goat serum, and I presume that Dr. Fisch killed his animals entirely too soon—namely, a month after infection, a period ordinarily insufficient for the development and recognition of tubercle.

I have previously published* some of my experimental work with Watery Extract of Tubercle Bacilli, and with other products derived from the culture fluid upon which tubercle bacilli had been grown.

More recently I have made another series of experiments with watery extract of tubercle bacilli, and with Koch's "Tuberculin R," which, though not entirely completed, appear to confirm my previous statement that these preparations are curative as well as protective.

Clinically, I have had the aid of several colleagues in endeavoring to find the best method of dosage, selection of cases, etc., and I am especially indebted to Dr. Charles Denison of Denver, and also to Dr. J. Longstreet Taylor of St. Paul, and Dr. John H. Williams of Asheville, for valuable assistance, they also having obtained valuable results from my preparation.†

In the study of the effect of the remedy I have found that it is also capable of producing reactions in the local tubercular area, which can be readily observed with the eye in tubercular infiltration in the larynx.

In the lungs also we note evidence of congestion in tubercular localities, and particularly in the outlying areas where more recent tubercles are present. Singularly, and contrary to the experience with crude tuberculin and its modifications, these local reactions are not usually accompanied with fever; on the contrary the temperature is frequently lower than before.

I have elsewhere‡ recorded my experience, which I believe justifies me in saying that any protid injected subcutaneously in sensible quantities is liable to produce fever. Blood-serum, solutions of egg-albumen, beef extract, beef peptone, and nuclein, all produce a rise of temperature after their hypodermic injection, and to all of these toleration can be established by beginning with small quantities, which when thereafter gradually increased even to very large doses do not disturb the temperature.

These substances have, however, no visible or apparent effect upon tubercular tissues,

* Cincinatti Lancet-Clinic, Feb. 8, 1898.
† Dr. Williams kindly put at my disposal the clinical data of twelve cases treated by him with my Watery Extract and discharged during the past year. They comprise seven early stage cases, all of which were discharged as cured; three more advanced stage cases, one of which was discharged cured, and two cases greatly improved; two cases in the third stage, of which one was cured, and one case (treated only three weeks) grew worse.
‡ New Orleans Medical Journal, July, 1898.
whether fever follows their injection or not —that is to say, we do not note the selective influence by which only tubercular tissues become injected and turgid. On the contrary, all we observe is the fever, with its general disturbance of the well-being of the patient.

For the production of fever with the various organic substances mentioned, much larger quantities than the amount contained in the maximum dose of the Watery Extract are necessary, and the non-occurrence of fever reactions from Watery Extract to doses of from \( \frac{1}{4} \) to three or four milligrams of organic substance may, perhaps, be thus explained.

In all my cases I have so gradually increased my doses that I have seen no unduly prolonged local effect, and I believe that such gradual increase is for the present the best and safest method of procedure. When a distinct local effect is produced, as evidenced by the temporary local congestion of the tubercular locality, I allow this to subside before I give another dose, which is usually the case in twenty-four to thirty-six hours. When the effect is unduly prolonged I reduce the next dose, and when no effect is produced I increase the dose.

Many physicians will of course be unable to observe and watch these local effects for a variety of reasons, and in such instances a very gradual and conservative increase is the best and safest course to pursue. A number of colleagues to whom I have supplied the remedy within the last eighteen months have been so circumstanced that no control as to reactions was possible, but they have obtained excellent results, nevertheless, though the treatment was somewhat prolonged.

From the reports that have reached me from such colleagues and from my own observation, I believe I am entirely safe in saying that if the increase is slow enough so that not more than 0.3 cubic centimeter of No. 10 solution is reached the first month, and the gradual additions to this dose do not exceed 0.5 cubic centimeter in subsequent months, no fear of undue reactions need be entertained, and the result will prove entirely satisfactory.

How satisfactory this may be, and how much visible improvement may be noted, will depend upon the pathological changes present, and also upon the additional care and treatment the patient receives. The latter will be more a factor the more advanced the case may be in destructive process, suppura-

tion, and softening in caseous localities, and in complications. In such cases the cough, fever, heart action, diet, and general conduct of the patient need careful attention and supervision.

I shall be glad at all times to supply as far as I have them reprints of articles on these and other subjects, in which I have recorded my experience.

It is chiefly in early and middle-stage cases, free from absorption fever, with a fair degree of nutrition, and free from serious complications, that I have obtained my best results, and I would urge those who desire to use the remedy under consideration to select only such cases, at least for a beginning.

In the observation of the involved lung portions and other tubercular localities, while the treatment is administered, I have rarely failed to note unmistakable changes for the better within the first month or six weeks, particularly in recent extensions to adjacent lung portions and to the opposite lung, and in recent infiltrations of the larynx.

Removable tubercles in the lung do not, however, as a rule reveal their presence by a dull percussion note unless the alveoli and bronchioles are entirely obstructed by their presence; nor do such tubercular deposits ordinarily cause bronchial respiration, much less coarse râles and rhonchi. On the contrary, the changes induced by purely tubercular deposits, especially when of recent origin, are delicate, and cause scarcely perceptible or but slight changes on percussion, while auscultation shows a weak, feeble respiratory murmur, which may be more or less rough on inspiration, when we also may note very fine crepitation. Later, after some months, the reactionary inflammatory changes in tissues, where tubercle has been formed, cause increase of connective tissue, and now the percussion changes become more marked while the respiration may become harsh and bronchial.

Many practitioners who are not in constant practice may have difficulty in making out these delicate changes, and if they fail to recognize them when the patient comes under treatment they will of course not note their disappearance later on. However this may be, they should not expect that the physical symptoms due to fibroid changes, caseous pneumonia, thickened pleura, and such like, will clear up and disappear under the use of this remedy, and if they cannot recognize the less pronounced changes they must be content to note the more general improvement
which always follows, unless in badly selected cases in which the irreparable conditions control the clinical course entirely.

Most cases coming under my care, even in advanced stages, present more or less recent extension of the tubercular disease in the lungs, which are destined to follow a like, but as a rule a more rapid and less favorable course than the earlier deposits have done.

It is not a matter of indifference whether these new deposits shall be allowed to remain and to undergo degenerative changes, or whether they shall be removed. If such cases are not already doomed on account of other irreparable conditions, the clearing up of such deposits removes a serious and often insuperable hindrance to their improvement, and to the arrest of the disease. This the Watery Extract of Tubercle Bacilli will do, even in advanced stages, when the patient’s nutrition is still fair.

Coming now to the result of the seventy-eight cases treated and discharged, I may emphasize again that the treatment was administered under ideal conditions in every respect, and I wish to again record my faith in the helpful influence of climate, and the advantages which a well conducted institution affords. The series is too long to record individually in a tabulated form, as such a table would occupy too many of the valuable pages of this journal.

The description of the cases appears in the report of the Winyah Sanitarium for 1898, and is at the disposal of any physician who desires it.

The same classification has been retained as in previous reports. The cases which are designated as “recovered” on their discharge showed no physical symptoms in the chest whatever. Where there were still evidences of the previous inflammatory process or healed cavities, the term “disease arrested” was added, which, of course, is not indicative of an absolute recovery, but relative only, the best that could be expected under the circumstances.

Among the seventy-eight cases were fourteen with tuberculosis of the larynx. In nine instances of more or less extensive tubercular infiltration of the larynx the infiltration disappeared under treatment in four, was greatly improved in two, and improved in three.

The stage of ulceration was reached in five cases. In one the ulcer was healed; in two others, nearly healed on their discharge; while one case was improved and one grew worse.

In addition to the specific remedy the usual local applications were made, but no curettage or other surgical procedures were employed.

The general improvement in this series of cases may be inferred from the almost uniform gain in weight, all patients but two having shown an increase over their weight on admission, and in many instances the patient was losing more or less rapidly on admission. In Class A, all patients gained weight, from 2 to 22 pounds, averaging 11 pounds each. In Class B, all patients gained from 2 to 44 pounds, averaging nearly 13 pounds each. In Class C, nineteen out of twenty-one patients gained from 1 to 25 pounds, averaging 10.5 pounds each.

A comparison of results obtained without specific treatment and with the various remedies employed was made in my last report; adding to this the seventy-eight cases reported here and treated with Watery Extract, the differences in results appear as follows:

These results speak for themselves; they were obtained in the same institution and under the same conditions in all respects, and justify the conclusion that in the production of the Watery Extract of Tubercle Bacilli as prepared by me we have made another and most valuable step toward the desired end.

ASHEVILLE, N. C., Jan. 1, 1899.
TWO UNRECORDED CAUSES OF DERMATITIS.

BY ANSTRUTHER DAVIDSON, C.M., M.D.,
Clifton, Arizona.

Eczema venenata as observed in southern California is almost invariably produced by the well known and all too common poison-oak of the foot-hills and mountains. In the eastern and midland States other species of Rhus cause a similar, though probably more severe, disease.

It is generally well known that there are numerous other plants the handling of which produces in susceptible individuals more or less acute desquamative dermatitis, closely resembling that produced by the common poison-oak. Many writers have spoken of these, and in our text-books are detailed a large number of plants that are capable of producing more or less irritation when freely handled. To this increasing list I shall add two others that so far as I am aware have not been previously recorded.

M. D., an intelligent young lady of very fair complexion, one day informed me that while she was always somewhat susceptible to the ordinary Rhus poisoning she was still more susceptible to poisoning by Solanum Xantii Gray, the wild potato so common in southern California. As the lady in question possesses a good knowledge of botany I had no doubt whatsoever of the truth of her observation, and asked her to kindly present herself at the office when next affected.

On June 15 she presented herself at my office with face and wrists almost completely covered with acute vesicular dermatitis. On the previous evening, while hitching her horse to a tree, she had stooped down to examine a flower. As the hour was late and the flower indistinct, she stooped low, and her face may have touched the plant, though she feels almost certain she did not come in contact with it, as on recognizing her old enemy she quickly withdrew. That same night pain, itching, and swelling began, and next day the face was in the first stage of vesicular eczema, with marked puffing of the eyelids. Two days after the face looked worse, but from that time on it gradually improved, passing through the regular stages of vesication and desquamation to final resolution. While the facial appearances in general closely resembled those produced by poison-oak, there were superadded all the more evident symptoms of belladonna poisoning. The pulse was rapid; on account of the extreme dilatation of the pupil she was unable to face a bright light; accommodation was paralyzed, reading being impossible. The dilatation of the cutaneous vessels of the face added that purplish look so characteristic of belladonna poisoning. The dilatation of the pupil persisted until the 18th. This time she informs me she has had no trouble with her heart, but with all of her previous attacks the heart weakness was so apparent that she was compelled to remain in bed for several days.

Here we have dermatitis produced by a member of a plant family noted for the poisonous qualities of its fruit and foliage, but not so far as I know locally injurious to the individual handling the plant. What produced the dermatitis in this case I do not know, nor can I explain the symptoms of belladonna poisoning otherwise than by saying the patient in question was peculiarly sensitive to the effects of belladonna.

The plant under review, as its name indicates, belongs to the Solanaceae, a family characterized by the presence of a number of potent and beneficial alkaloids, such as dulcamarine, atropine, hyoscyamine, lycine, and dubeoine. How many of these alkaloids other than atropine exist in our plant I have no means of determining. None of the Solanums that exist in California are reputed poisonous. The very noxious Solanum nigrum, which in Europe proves so frequently fatal to children who eat the berries, is here represented by the variety Douglastii, and not only is it eaten with impunity, but actually with relish by thirsty children.

Another plant which frequently causes dermatitis is our common and much appreciated fig of cultivation. Among the fig-pickers, especially if children, cases of dermatitis are far from rare. I have seen a few individuals who are so susceptible to injury from the fig that they carefully avoid picking the fruit from the tree. Eating figs already plucked has no injurious effect, as the dermatitis produced is not, as in the poison-oak, due to the chemical irritants contained, but to the brittle hairs that cover the leaf, especially on its surface. In the act of picking the fruit these prickly hairs readily penetrate the flexor surfaces of the fingers and wrists, and in individuals with irritable skins a dermatitis follows in twenty-four hours, each hair having produced a minute papule with a small inflammatory area surrounding it. The dermatitis is probably produced by the mere mechanical presence of the bristle-like hairs,
as examination shows that the hair points are solid at the tip and that the basal part of the hair, which at an early stage is filled with fluid, is at the time of ripening of the fruit filled with air only. From the fact that children with their delicate and irritable skins most usually suffer from this form of dermatitis, one is led to presume that Eve when she adopted the leaves of the fig as the primary article of raiment must at least have passed the age of puberty.

The dermatitis produced by the hairs on the fig-leaf, I need scarcely add, is readily subdued by simple emollients.

THE OPERATIVE TREATMENT OF VARICOSE VEINS OF THE LEG.

BY EDWARD MARTIN, M.D.,
Clinical Professor of Surgery, Women's Medical College;
Clinical Professor of Gynæo-Urinary Surgery, University of Pennsylvania; Surgeon to the Philadelphia, St. Agnes, and Howard Hospitals.

In bringing up the subject of the operative treatment of enlarged veins of the lower extremity I have no intention of speaking of the etiology of this affection. Those who are interested in the various theories advanced to explain the relative frequency of varicosities of the leg I would refer to Dr. James J. Walsh's excellent paper, which has recently appeared in the University Medical Magazine. My own belief is that this disease is in many cases dependent not so much on venous stasis incident to intra-abdominal pressure, as it is upon the incompetency of the valves, and that this incompetency in turn is dependent on congenital formation rather than upon acquired pathological conditions. Certain it is that varices form in otherwise healthy individuals without appreciable cause, that they form in the vein least protected by valves and which would naturally suffer most from hydrostatic pressure, and that they have been relieved and cured by the application of an artificial valve—i.e., a water pad placed over the trunk of the internal saphenous near its origin.

Congenital valvular insufficiency will explain many of these cases of varicosity of the long saphena and its branches, which are not due to external obstruction, violent straining, or thrombus.

Aside from the weight, aching, and at times acute neuralgic pains dependent upon varicose conditions of the veins of the leg, and the infiltration, inflammation, and ulceration of the skin and subcutaneous tissues, there is danger of severe hemorrhage from bursting of the vessel. I personally know of two fatal cases, and numbers are reported and still others have never found their way into surgical literature. This hemorrhage is, of course, readily arrested, but unfortunately it is liable to occur when skilled help is not at hand.

Moreover, it can readily be fancied that in some of the enormously dilated veins which are occasionally seen the diversion of such a large quantity of blood from the general circulation might seriously influence general health.

Thrombosis with consequent embolism is also an ever-present danger, especially in varicosities about the knee, and though this complication is rare it is one of exceeding gravity.

As to the relative frequency of varicosities, at least those sufficiently advanced to produce serious inconvenience or even disability, I believe there is some misconception. In the management of a number of large surgical services in the city I have been surprised at the relatively small number of patients presenting themselves for relief from this affection. Out of 12,806 surgical dispensary cases taken from the reports of several hospitals, but forty-three are reported as suffering from varicose veins—about three-tenths of one per cent of the total number. In the summer, wishing to give a special form of operative treatment a careful trial, I requested my residents at the Philadelphia Hospital to scour the female out-wards for patients on whom it would be justifiable to perform a radical cure. These are taken from the classes who are peculiarly prone to this affection—that is, the poorly nourished and hard-worked—and the great majority of them are past middle life. Of the total number I found but a single case of enlarged vein sufficiently pronounced and sufficiently discomforting to the patient to make me feel justified in suggesting operation. This was promptly refused.

It is undoubtedly true that the great majority of the cases observed can be treated satisfactorily by palliative means, notably by the truss and by the elastic bandage. In either case the appliance should be removed at night and should be reapplied before arising in the morning.

The indications for operation are: (1) A varicose condition steadily increasing in spite of palliative means, and particularly the pres-
ence of veins so dilated and attenuated that slight trauma may occasion hemorrhage; (2) intractable ulceration, infiltrations, or inflammations of the skin and underlying tissues; (3) present or prospective disability; (4) the occurrence of thrombi, particularly about the knee-joint and above it.

Injections of coagulating or irritating substances with the object of causing inflammation and subsequent cicatrization were at one time popular. Stevenson (London Lancet, ii, 769, 1886) employed carboic acid. He thus treated eight cases, injecting one minim of the pure acid at several points in the vein, a ligature first being placed about the limb high up. Schede quotes Soquet and Guillermond as having reported sixty cases treated by the injection of tannate of iodine. Boigut recommends injections of ergotin. Isaac injected a five-per-cent solution of sulphate of iron. Bryant injected tannin into the tissues lying about the vein. This method is dangerous and futile.

Ignipuncture is advocated by Tillman and a few of his followers, the point of the galvanocautery or Paquelin being employed.

Herepath advised subcutaneous nicking of the borders of the saphenous opening, with the idea of thus doing away with any obstruction which might be caused by this tough fibrous band.

Acupression has had many advocates, among them Davitt, Fergusson, Lea, Velpeau, and Frickel.

Rigaud reports 160 cases cured by dissecting the vein through a small incision and exposing it to the air. Gangrene subsequently took place at the point of exposure. He lost three cases from pyemia. He very justly concludes that this method is extremely dangerous and unreliable and recommends division between ligatures under the strictest antisepsis.

Retrenching of the skin with the idea of making this serve as an elastic stocking has been practiced by a number of surgeons. Lang quotes a case of Macaren's, this surgeon having taken an elliptical piece of skin from the back of the leg, reaching from the popliteal space to the tendo Achillis, and having obtained good results.

All these methods may be fairly considered out of date, and there remain to be considered: (1) single ligature of the saphenous vein high up (Trendelenburg's operation); (2) multiple ligature through the entire course of the varicose veins, first popularized by Phelps; (3) extirpation of the greater part or all of the dilated vein, or Madelung's operation. The names of the surgeons are thus associated with a particular operation rather because they have popularized these procedures than because they have originated them, since, for instance, resection of the vein was advocated by Celsius, and the principle of single ligature high up and multiple ligature was practiced long before the era of antiseptic surgery.

Considering these three operations, the easiest and quickest is that of high ligation. The long saphenous vein is exposed shortly after it leaves the saphenous opening, two ligatures are applied, the vein is divided between these ligatures, and the small opening is closed by a stitch. A bandage and splint are then applied and the patient is kept at rest for one or two weeks. The whole operation can be completed in three or four minutes and does not require a general anesthetic, eucaine B rendering the procedure entirely painless.

Multiple ligation as performed by Phelps is also rapidly accomplished, and it is practicable to do it under local anesthesia. He has operated on upwards of 200 cases of varicose veins of the leg without a death, and in so far as immediate results were concerned without a single failure. His method is that of multiple ligature with catgut. He aims at entire occlusion of the dilated vein, throughout its whole length, and has applied as high as sixty or seventy ligatures, the distance between these ligatures being from one inch to an inch and a half. The thread is placed subcutaneously—that is, a flattened needle threaded with catgut is driven beneath the vein, is unthreaded, is then carried over the vein through the same opening, is rethreaded, and on withdrawal of the needle the vein is included in the ligature, which is tied down tight, the knot being pushed into the skin if fine catgut is employed. The limb is splinted and the patient kept in bed for two weeks, and after that a roller bandage is applied for about two months.

This method is open to the objection that it is often difficult to pass the needle under instead of through the vein, and that the needle is liable to puncture the branches, penetrating through the deep fascia. These objections are by no means insuperable, and the permanent value of the operation must depend upon ultimate results. The total excision of the varicosity is the most difficult and tedious of all operations, and though it is
practicable to perform it under local anes-
thesia the majority of surgeons will probably
still continue to employ a general anesthetic.

As a modification of a total excision, mul-
tiple resection commends itself as a valuable
procedure, but it is worthy of note that the
great majority of surgeons who have written
on this subject are strongly inclined to favor
total excision. Boennecken, Bennett, Mc-
Kay, Maylard, Hause, Rogers, Duchamp,
Wyman, Jonas, Remy, Dambrowski, Soldani,
Rema (who obtained ten cures, twenty-two
non-successes, and two deaths in thirty-four
cases), White, and many others are warm
advocates of this method.

High ligation of the saphenous and divi-
sion between ligatures has almost as many
advocates. Tillman states that Trendelen-
burg has practiced this simple operation for
many years with the very best results, and
that he considers it the best treatment for
varices of the leg.

Prawdoljubow reports eight cases thus
treated, with entire success. Wolff has thus
successfully operated on twenty-two cases,
employing only cocaine anesthesia. In every
instance great symptomatic relief followed;
the ulcers, eczema, and hemorrhages per-
manently subsided. He states that a good
temporary result is always seen, but is not
willing to speak definitely in regard to final
results.

Remy employs both methods. Schede,
van Hoeter, Schwartz, and Fokker favor the
Trendelenburg method. Zeses recommends
multiple resections, and states that Starke, of
Berlin, has reported thirty cases, all success-
ful. Hause also reports ten successful cases.
Savory also recommends multiple resections,
holding that extensive dissection is danger-
ous and unnecessary.

My personal experience in the operative
treatment of varicose veins has been limited
to six cases. Four of these cases were men,
two were women; three were complicated by
edema, eczema, and intractable ulceration;
in five the long saphena and its branches
alone were involved; in one both the long
and short saphene.

Two cases were treated by multiple ligation,
eight ligatures being used in one, twelve in
the other. The vein was exposed by a cut
half an inch long, was ligated with catgut in
two places and cut between. It was splinted
for twelve days, and the patient was then
allowed to be up with a neatly applied band-
age.

The immediate effect was good. Standing
and walking produced no sense of fatigue,
and though the dilatation between the sets
of ligatures remained after operation, it gradu-
ally grew less and was not materially in-
creased by the standing posture. In one
case at the time of operation the veins were
found full of a soft thrombus. This was
squeezed out, but subsequently reformed,
and the leg remained tender and edematous
for over a month. Both cases healed by
primary intention.

One case was treated by multiple resec-
tions, six cuts being made, and from two to
four inches of vein being taken out at each
point. The immediate result in this case was
more gratifying than was that from multiple
ligation. The varices had almost entirely
disappeared, and the subjective symptoms
were relieved.

Three cases were treated by extensive re-
section. In two the incision was made di-
rectly over the course of the vein; here the
skin was so thin and its vitality so impaired
that the wound was slow in healing, although
it remained entirely clean.

The results in these cases of extensive re-
section were better than those obtained by
either of the other two methods. In the last
case operated on thirty-seven inches of vein
was removed. It was the most marked case
of leg varix I have ever seen, the tortuous
dilated vein forming a mass the thickness of
a man’s forearm, beginning three inches
below the saphenous opening and running
down below the middle of the calf. In this
case the incision was made in the form of a
flap. Thus the greater part of it was carried
through healthy skin. This skin was dis-
sected back, the vein was then tied above,
about two inches below the saphenous open-
ing, and was dissected downward. The pa-
tient had suffered for years from marked solid
edema and a deep indolent ulcer, which had
resisted absolutely every form of palliative
 treatment. He was a glass-blower by trade.
I operated on him July 12, 1894. I have re-
cently heard from Dr. Herbert Carpenter,
of Salem, N. J., whose patient he was, who
states that his ulcer healed promptly and the
edema has disappeared. Since then (more
than four years) he has been working steadily
at his trade of glass-blowing with no sign of
recurrence. The other saphenous vein was
also varicose, but was not touched. It re-
mains in the same condition.

I believe that all three of the methods at
present in vogue have their proper appli-
cation. When the varix is moderate in degree,
even though extensive, and where the vein is
dilated high up, the high division between
ligatures, performed under cocaine, should be
given a trial. Should this fail and should
the vein be moderately dilated, either mul-
tiple ligation or multiple small excisions
would be indicated. When the veins are enormously
distended and tortuous, and particularly when
they contain sacculations and thrombi, total
excision is indicated.

All of these methods of treatment should
be supplemented by rest in bed for two weeks
with careful splinting and by the wearing of
a carefully applied bandage for at least a
month. Operative dangers and complicat-
tions are no longer to be feared.

THE TREATMENT OF HEART DISEASE
IN CHILDREN.

At the last Congress of Gynecology, Ob-
sterics, and Pediatrics, held in October, 1898,
Weill read a paper upon this subject. In
congenital lesions we are utterly unable to
do any material good; but in acute endo-
carditis in which there is danger of the de-
velopment of severe valvular lesions, preventive
medicine can do much. The endopericarditis
of rheumatism is affected little if at all by the
salicylates, yet it is in rheumatism that these
lesions most frequently occur. In typhoid
fever with a tendency to heart disease the
cold bath is exceedingly efficacious as a pro-
phyllactic against cardiac lesion. Antidiph-
theritic serum is to be used as a prophylactic
in diphtheria, and antistreptococcic serum in
scarlatina. He thinks salicylate of sodium is
of little avail as a direct remedy in rheu-
matism of the heart, but its use shortens the
attack and is thereby of value. It is well
borne by children, and rarely produces vomit-
ing, vertigo, or roaring in the ears, if given
in the dose of seven grains a day in the first year
of life, fifteen to thirty grains up to the third
year, and forty to seventy grains at ten years.
The diet should also be carefully attended to.
Milk, soups, and absolute rest are to be
resorted to, the heart quieted if necessary by
the use of small doses of bromide of potas-
sium and digitalis, and insomnina, if marked,
combated by sulphonal or trional.

To still further combat endopericarditis
Weill suggests inunctions over the precor-
dium, the application of cold, the applica-
tion of flying blisters, and if the patient is
strong, venesection. (With this latter plan
of treatment we cannot at all agree.—Ed.)

Where actual valvular changes exist blis-
ters over the precordium, or even the appli-
cation of a hot iron, are recommended, and
the administration, internally, of iodide of
potassium for fifteen or twenty days in each
month in the dose of three to ten grains, given
after two meals in a glass of milk. He thinks
that about six out of every 100 cases of rheu-
matism in children die from rheumatic peri-
carditis, and that after the disease becomes
at all subacute we can do little to relieve it.

Should the pericardial effusion become pu-
rulent it must be allowed to escape by means
of an incision. After a valvular lesion has
become chronic it is necessary to improve the
condition of the heart muscle by a stimulant
and nutritious diet. The patient must be con-
tinually in the fresh air. Rubbing must be
resorted to to improve the peripheral circula-
tion, and gymnastics with Swedish movements
and hydrotherapy employed. Care must be
taken to exercise all the muscles of the body,
but not to tire them, and violent exercise must
be absolutely prohibited. Such games, for
example, as football and tennis, and long
walks, are not to be permitted. Bicycle
riding may be utilized in moderation, but
great fatigue must not be allowed. Regular
hours must be insisted upon for meals and
for retiring. The digestive tract must be kept
in good order. Severe mental work ought
also to be prohibited. In paroxysmal dyspnea
coming on in heart disease absolute rest,
counter-irritation in the form of a mustard
plaster over the 'precordium, and the admin-
istration of diffusible spirits, are to be resorted
to. Subcutaneous injections of camphor, cafe-
eine, and ether are useful, and inhalations of
oxygen and nitrite of amyl may be used.
Should there be pulmonary congestion with
albuminous expectoration, active counter-
irritation should be applied to the chest.
Should great cardiac excitement be present
digitalis or caffeine may be needed. If cough
is present the administration of sedative sub-
stances, such as iodide of ethyl, pyridin, anti-
pyrin, and bromoform, may be given. The
caffeine may be given in the dose of one to
two grains a day to a child of from two to
five years, and four to seven grains a day
to a child of seven to fourteen years. If it
is desired to give it hypodermically the fol-
lowing solution may be used:

B  Benzoate of sodium, 45 grains;
Caffeine, 30 grains;
Distilled water, 2 3 drachms.

A small hypodermic syringeful of this may be
given once or twice a day.—Revue de Théra-
peutique Médico-Chirurgical.

FATAL EFFECTS FROM MERCURIAL INUNCTIONS.

Mercury is given in so many forms, and so often, to patients without producing other results than those which are good that instances in which it is administered with disastrous effects are of very considerable interest. In the vast majority of cases in which evil effects follow the employment of this drug the symptoms consist chiefly in more or less severe evidences of salivation which force themselves upon the attention of the patient and physician so early that the administration of the drug is stopped before any serious damage is produced. Sometimes, too, when mercurial inunctions are used for the removal of parasites, or in the treatment of syphilis, and active care is not exercised in the maintenance of cleanliness of the mouth, similar disagreeable symptoms ensue; and it will also be recalled that a large number of cases of subacute or chronic mercurial poisoning occur in artisans working with mercury, although in the great majority of instances the symptoms manifested under these circumstances have been those of disorder of the nervous system rather than disorders of secretion. In this connection a case which has recently occurred in Belgium is of very considerable interest, and notice of it has been taken in a recent number of the London Lancet. It seems that one physician was the only medical man appointed to take charge of the patients in a very large workhouse which contained no less than 4000 inmates, and that attached to this workhouse there was also an infirmary which contained from 100 to 200 patients, and that he was also in sole medical charge of 125 officials and their families, some of whom resided at a considerable distance. Because of the large amount of work which accumulated the medical officer issued an order that all infirm inmates who were admitted and suffering from vermin should receive as a routine treatment an inunction of a compound of two parts of strong mercurial ointment with three parts of vaselin, followed an hour later by a bath. The average quantity of ointment employed was about one drachm, and this treatment was carried out in about 630 patients, of whom thirty showed signs of mercurial stomatitis, seventeen of them being confined to the ward and three of them being ill enough to be taken into the infirmary. Of these three one died. He was sixty-seven years of age, and his death did not occur until a month after the inunction had been given; nevertheless the medical officer was arrested charged with manslaughter. In the medical expert evidence of the courts it could not be proved that this treatment was responsible for the death, although from the fact that an "ulcerogangrenous" condition speedily occurred it seemed as if it were the provoking cause. To make a long story short, the physician was fined fifteen francs on the ground that such heroic measures were not suited to all persons and that it should not have been prescribed indiscriminately without a medical examination. This judgment was appealed from and the defendant was finally acquitted by a higher court.

Considering the circumstances this verdict of acquittal was eminently just. It is quite possible that in such a large proportion of patients one might readily be found with an idiosyncrasy to mercury, and the labors required of this individual physician were so excessive that manifestly the blame for the accident should rest upon those who were so niggardly with their appropriations rather than upon the medical man in charge.
THE EXCESSIVE USE OF ALCOHOL.

The editorial pages of the Therapeutic Gazette have heretofore contained material dealing with this important question, and in these articles we have endeavored to show that while alcohol is a drug which is greatly abused, it is also one which, when properly employed, is, like any other powerful drug, capable of producing very good results. As persons interested in the study of the social side of mankind as well as in his physical diseases, it is interesting for physicians to note how this drug when employed by the laity without medical advice is abused. That it is so abused by the laity every one knows, and none are so blind that they cannot see it. In this connection, an article upon alcohol which has been published by Debove in La Presse Médicale of November 16, 1898, is of very considerable interest. After reviewing a certain amount of historical data concerning this subject, he points out that it may be studied under four headings, namely, the consumption of alcohol, the effects of it on the individual and on the race, alcohol as an agent in producing intoxication, and the prophylactic measures which are to be used against the increase in alcoholism. He then points out what enormous quantities of alcohol are consumed in alcoholic beverages in France. Thus as much as 2,000,000 hectoliters of alcohol are used a year, according to official reports, and as a considerable quantity is manufactured and taken secretly the total quantity consumed is even greater than this. As much as 500,000 hectoliters of brandy are used. There has also been a steady increase for years in the quantity of alcohol which is ingested. Thus, in 1850, 1.46 liters of alcohol was consumed by each inhabitant; in 1860, 2.27; in 1880, 3.64; in 1895, 4.7; in 1896, 4.19. In addition to this there is an annual consumption per head of 25 liters of beer, 18 liters of cider, and 79 of wine, which represents about 10 liters of alcohol.

The actual consumption of alcohol in various countries is illustrated in the following statistics. It is of very considerable interest, as it shows what an extraordinary degree France surpasses all other nations in the consumption of alcohol. Thus France uses per head 14 liters of alcohol to each individual, Belgium 10, Germany 10, Great Britain 9, Switzerland 8, Italy 6, Holland 6, United States 6, Sweden 4, Norway 3, and Canada 2. Statistics in regard to these countries, unlike those of France, show that they are using very much less alcohol to-day than they did twenty or thirty years ago. Thus the consumption in the British Isles has decreased slightly, in Italy it has decreased about one-half, in Switzerland it has decreased one-half, in Germany about one-half, and in the United States about one-half. Not only has the consumption of alcohol increased very materially in France, but, as might be imagined, the number of places at which it is retailed has also increased; thus in 1830 there were in France 281,000 public houses, but in 1897 there were 500,000, and in the Department du Nord there is one public house to every forty-six inhabitants, or to every fifteen adults. In the Department of La Seine-Inferieure there is one for every seventy inhabitants, or twenty-two adults, and in Paris there are no less than 33,000 public houses, which is more than one to every three other houses. Nor does the sale of alcohol stop here, as Debove points out, for it is sold upon railway trains and even upon the tramways at points where traffic is temporarily interrupted by change of cars. Resorting to cafés in his opinion increases its use amongst women and children as well as amongst men. Debove then goes on to express his views as to the enormous expenditures which are made by the French people in the purchase of these quantities of alcoholic beverages.

SALICYLATE DELIRIUM.

Perhaps it is not as well recognized as it should be that large doses of the salicylates are capable of producing cerebral disturbances, which are naturally of a fleeting character, in that they disappear almost as soon as the administration of the drug is stopped. It will be remembered that Strümpel has recorded cases of active delirium occurring after full doses of salicylic acid, this delirium being happy in its type and occurring most commonly in young girls. In other cases full doses produce visual disturbances, which are most marked when the eyelids are closed. In this connection it is interesting to take notice of a case reported by Rendu at a recent meeting of the Société Médicale des Hôpitaux. It was that of a woman of thirty who was admitted to the hospital owing to an attack of subacute polyarticular rheumatism. An examination of the urine showed it to be normal, and no visceral lesions existed as complications. The salicylate method of
treated rheumatism was at once instituted, as much as 1½ drachms of salicylate of sodium being given each day. At the end of thirty-six hours the joint symptoms had almost disappeared and the fever was completely dissipated. That night after a chill she became violently delirious, had hallucinations of sight and hearing, with extreme agitation, and could only be restrained by force. The temperature rose several degrees; the urine was abundant and contained considerable quantities of albumen and indican. The tendency was to regard the rise of temperature and the cerebral manifestations as signs of cerebral rheumatism, and the possibility of uremia was considered. Finally it was decided, however, that the symptoms were due to salicylic intoxication. Salicylate of sodium was therefore stopped and sixty grains of bromide of potassium administered; a hot bath was also given of half an hour's duration. A milk diet was ordered. At the end of two days the patient was much better, and the joint symptoms, which had temporarily become slightly worse, were relieved by the use of antipyrin and sulphur baths.

The points which Rendu thinks are noteworthy in this case are the invasion of the symptoms without prodromes, the absence of headache and roaring in the ears, and the presence of acute delirium of maniacal form. Secondly, he thinks that the albuminuria with production of enormous quantities of indican were due to the introduction of the salicylate. Third, he does not think that they were due to uremia from renal irritation caused by this drug. The antecedents of the patient were not such as to indicate that she would have an idiosyncrasy to the drug, and a final examination of her urine on her recovery failed to indicate any disease of the kidneys.

THE TREATMENT OF TRAUMATIC TETANUS BY ANTITOXIN.

It is now several years since tetanus antitoxin serum has, on the basis of laboratory experiments, been presented to the profession as both preventive and curative of tetanus.

Though the preventive power of the serum seems to have been thoroughly proven from an experimental standpoint, convincing evidence as to its clinical value is still wanting. It has been used when wounds were of such nature as to make the development of tetanus not unlikely, and apparently successfully. Negative evidence of this nature must, however, be cumulative before it is of special value, and the record of a few cases carries with it absolutely no weight. It cannot, however, be gainsaid that the arguments in favor of preventive treatment by timely injections of immunizing serum are so strong that, with the evidence before us as to the comparative innocuousness of these injections, measures of this nature would be justified when punctured or lacerated wounds have been soiled by earth, and especially by that about stables, or when there are other reasons for supposing that tetanus may develop.

As to the curative effect of the antitetanic serum after the disease has once thoroughly developed, the case stands, as it has for the last two years, sub judice.

It is true that large numbers of cases have been collected, and that from them a mortality very much lower than that attributed to the disease before the advent of the new treatment has been calculated. In studying these cases, however, it will be noted that those which recovered were, with almost no exception, of the subacute type—developing more than five days from the date of infection, running a comparatively slow course, and of a nature similar to that which is typical of the cases which frequently recovered before the antitoxin treatment was known.

If the curative effect of the antitetanic serum were proven, it would be the duty of every hospital, and of every physician and surgeon, in the country to have a supply of this new and exceedingly costly drug at hand. The failure of a large number of hospitals, and of the great bulk of the profession, to take such measures that they may thus be provided at short notice, abundantly proves the lack of confidence with which this modern method of treatment is still regarded.

As a further important modification of the serum-therapy of tetanus, Roux and Borrel's intracerebral injections are worthy of comment. This method of treatment is based on certain laboratory experiments. They found that if a mixture made by rubbing together brain substance and tetanic toxin were centrifugated the upper liquid layer of the resultant mass contained very little toxin, whilst the thick lower one, representing the nervous substance, held practically all; thus showing that the poison was taken up by the nerve cells. They also noted that immunized rabbits perished from the intracerebral injection of a dose of toxin, which could have been injected hypodermically.
without causing symptoms of any kind; but that if to the dose capable of causing death when injected intracerebrally a drop of blood from an immunized rabbit were added, the injection would prove innocuous.

As a conclusion to these experiments Roux and Borrel hold that the toxin of tetanus is fixed in the nerve cells, that the antitoxin remains in the blood, and that a curative serum injected into the blood is powerless to neutralize the poison which has already entered the nerve cells, because it cannot be reached.

Tetanized guinea-pigs treated by intracerebral injections mainly recovered. Nearly all subjected to intravenous injections died.

Thus to protect the brain and upper part of the cord from tetanus, antitoxin must be introduced directly. It cannot cure the lesions, and if the medulla is poisoned at the time of injecting, as shown by impaired swallowing power and respiratory changes, the treatment cannot be curative. If, however, intracerebral injection is made before the toxin has been absorbed by the nerve cells of the vital centers, the latter may be protected against the injurious effect of the absorption.

As to the clinical results following intracerebral injection of antitetanic serum, Ram- baud has collected twelve cases from foreign literature, eight of whom perished. Of the four successful cases, the incubation in one was fourteen days; in two it was unknown, there being no wound; in one it was twelve days. Apparently none of these were of the fulminant class. Three cases have been treated by the new method in this country. The first one developed tetanus after laparotomy, the incubation being ten days; the patient recovered from tetanus, but died about three weeks after the injection of acute nephritis. The second case had an incubation period of twelve days, and was in the seventh day of a mild tetanus when the injection was performed. The third case had an incubation of seven days; he died twelve hours after injection. Until a better showing is made for treating tetanus by trephining and making intracerebral injections, the profession can resort to other and simpler means with a clear conscience.

---

THE TREATMENT OF BLOOD EFFUSIONS INTO THE KNEE-JOINT BY PUNCTURE.

It has been sufficiently proven, both by experimental research and clinical observation, that blood effused into the knee-joint as the result of traumatism, in the main remains liquid unless the injury be of such nature as to cause fracture of the bone or very serious injury to the joint structures. As a rule the fluid blood is quickly absorbed. Even when the blood clots it is usually absorbed, but more slowly, so that after about three weeks there will remain no trace of hemorrhage excepting some pigmentation. The rapidity of this absorption is in inverse ratio to the severity of the lesion.

Although the prognosis of traumatic hemarthrosis is in the main good, it must be borne in mind that extreme tension greatly retards absorption, weakens the soft parts of the joint, and may be followed by a chronic hydrarthrosis. Exceptionally ankylosis may result from organization of the blood-clot with the ultimate formation of fibrous tissue.

As to the treatment of hemarthrosis, Vollmann advised, even in the preantiseptic period, that when the knee-joint was so greatly distended with blood that a fracture, such as that of the patella, could not be properly adjusted, the blood should be evacuated. In the absence of such an injury he advised puncture when the swelling incident to bleeding was very great.

Lübbe (Deutsche Zeit. für Chir., 49 Bd., 6 Heft) holds that there is every reason for puncture in all cases of pronounced hemarthrosis; since thus is removed quickly and without danger a foreign substance which may lead to entire destruction of the joint. Of thirty-two cases thus treated in the Sailors' Hospital at Hamburg, the average duration of treatment was twenty-two days. Of twenty-two cases treated without puncture, the average period of treatment was thirty-four days. This contrast is still more striking if it be borne in mind that only the most pronounced cases attended with greatest swelling were punctured, whilst those characterized by only moderate swelling were treated conservatively.

Bondsen arrived at practically the same results from his experience at the Copenhagen Hospital. Moreover, the percentage of cases completely cured is much larger after operative treatment. A very protracted convalescence was never noted after puncture.

The instrument used was a large trocar. The operation was performed but once and immediately after the patient was taken into the hospital; the joint at the same time being washed out with either a two-per-cent carbolic solution or 1-to-5000 sublimate lotion.
In no instance was this procedure followed by bad results. The after-treatment was that common to contused joints—i.e., immobilization and pressure until the inflammatory reaction subsided, and after that massage.

This treatment, which has been strongly advocated by many of the ablest surgeons, is one which has not yet become popular because of the fear, often well founded, of infecting the joint, and thus subjecting the patient, whose chances of recovery are good, to the loss of a limb, or even to the loss of life, by an operation having for its object the allaying of pain and the shortening of the period of convalescence. Modern technique has, however, reduced the danger of infection so nearly to the vanishing point that it may be disregarded. When it is considered that the effusion of blood if left to Nature's resources may entirely destroy a joint—that that it is extensive and produces great tension the joint at the best is likely to be permanently weakened—the operation of puncture seems to be fully justified, not only immediately after the infliction of the injury, but after some weeks when it is apparent that the blood is not being absorbed.

Reports on Therapeutic Progress

ACUTE AND CHRONIC MIDDLE-EAR SUPPURATIONS: THEIR TREATMENT.

In the Clinical Journal of October 5, 1898, De Santi tells us that in middle-ear disease the following are the lines of treatment, modified, of course, according to the severity of the symptoms: The patient should be kept quiet both mentally and physically, given a good saline purge and a light diet. If there be severe pain, febrile symptoms, and considerable hyperemia, the patient being a healthy adult, the local abstraction of blood by means of leeches (eight to twelve for an adult, two to four for a child) applied to the mastoid region, or tragus, and followed by the application of warm fomentations, will give relief.

In less severe cases, or in people with broken-down health, where bleeding is contraindicated, warm sedative poultices may be applied externally, or medicated applications be instilled into the ear every three or four hours. Of such applications solutions of opium and belladonna, of morphine (two grains to the ounce), of simple tincture of opium, are the most useful. A few drops, eight to ten of the particular solution selected, are warmed and dropped into the ear, and the canal closed with a pad of cotton-wool.

In private practice a convenient form of medicament consists of aural ovoids. They are capsules of gelatin containing one-sixth grain of liquid extract of opium, or one twelfth grain of hydrochlorate of morphia, and are introduced deeply into the auditory canal with aural forceps, the meatus being then closed with cotton-wool. The capsule gradually dissolves and the pain is relieved. Should the pain be so severe as to prevent sleep, ordinary internal narcotics are indicated.

When the pain, notwithstanding this treatment, continues, and there is evidence of a collection of pus in the middle ear, as revealed by yellowish bulging of the membrane, it is necessary to take measures to evacuate the pus in accordance with ordinary surgical principles.

It is of especial importance not to delay, for the tympanic cavity is in anatomical relationship with most important parts, and it is no exaggeration to say that a timely incision may be the means of saving the life of the patient. Moreover, paracentesis or incision with a myringotome not only gives exit to the pus in the tympanic cavity, but by division of the vessels reduces the hyperemia and lessens the amount of damage which usually occurs in the membrane from spontaneous perforation; this is particularly the case when scarlet fever is the cause of the inflammation.

The operation is most conveniently performed as follows: The external auditory meatus having been thoroughly cleansed and dried, a fifteen- or twenty-per-cent solution of cocaine is sprayed on to the tympanic membrane, a suitable speculum inserted, and a good light reflected down the canal. If from the swelling of the external meatus the membrane tympani cannot be seen, it is wiser to stick to fomentations, etc.

The patient's head being held by an assistant, the membrane is freely incised from above downwards with a myringotome in the situation where there is the greatest bulging, or, if general, behind and below the handle of the malleus.

It is of importance that the incision should be a free one, as the contained pus is often thick and viscid, and moreover there is a tendency for the artificial perforation to close up too soon. After incising the membrane
the middle ear should be inflated with Politzer's bag or a Siegle's pneumatic speculum, to drive out as much pus as possible.

The auditory canal is then closed with aseptic cotton-wool; the incision must be kept patent so long as there is any discharge of pus. The patency of the artificial opening is best assured by free incision and daily Politzerization; but should there be a tendency for it to close too soon, a probe should be frequently passed through the aperture. Antiseptic cleansing should be carried out twice a day, and a lotion prescribed for syringing the nasopharynx, otherwise the condition is apt to become chronic.

In the early stages just subsequent to perforation the author orders the following treatment to be carried out: The ear to be carefully and gently syringed three or four times a day with a warm solution of boric acid (eight grains to the ounce). Whilst part of the solution is still in the meatus inflation by Valsalva's or Politzer's method is employed; this forces some of the intratympanic secretion out into the meatus, from whence it can be removed by again syringing out. The ear is then carefully dried and gently plugged with absorbent wool.

If the discharge be slight in amount syringing should be employed less frequently, and after drying the ear small quantities of finely powdered boric acid are insufflated. Under this treatment recent cases will get well in a few days to a month. It is generally necessary that the practitioner should carry out the treatment himself, or else thoroughly instruct the patient's friends in the act of syringing and cleansing, so that it shall be properly done.

Among the author's notes he finds records of several such cases, cicatrization having taken place within a month or less. Perforations due to trauma and followed by suppuration, as a rule do particularly well under the above treatment. He has had recently two such cases: in one, a lad aged eighteen, the drum was perforated by the spoke of a bicycle wheel and suppuration ensued; in the other, a lunatic girl, the perforative otorrhoea was caused by a rusty nail secreted in the meatus. Both cases were cured within three weeks.

Chronic cases, which unfortunately are by far the most common, are often extremely difficult and even impossible to cure.

The general lines of treatment should be:

Thorough cleansing and disinfection of the cavities of the middle ear.

Appropriate treatment of the nose, nasopharynx, and throat.

Careful general treatment, especially with regard to such diatheses as tubercle, syphilis, etc.

Thorough cleansing and disinfection of the cavities of the middle ear are of the greatest importance, and such treatment is only in accordance with ordinary surgical principles.

Two methods may be employed—the moist and the dry. The former is applicable when there is profuse and fetid discharge; the latter when syringing causes pain or giddiness, where the discharge is slight and non-fetid, and in cases of old quiescent perforations (if they are treated at all). The author carries out the moist treatment thus: Thorough syringing of the ear with warm boric lotion (100°–102° F.); inflation of the middle ear by Valsalva's or Politzer's method, and careful drying of the parts with absorbent wool-wicks twisted on an aural probe; finally, he insufflates a very little finely powdered boric acid on to the diseased mucous membrane of the tympanum, and lightly fills the outer half of the external meatus with a plug of salicylic wool. If the discharge be very profuse, he orders this treatment to be carried out three or four times a day. As the discharge lessens; the syringing, inflation, drying, and insufflation are less frequently done, until finally the powder remains dry for days or even weeks.

This treatment may have to be persevered in for a considerable length of time before a permanent cure results; if no benefit accrues after a thorough trial, other methods or medicaments must be employed.

Of course, such complications as granulations, polypi, caries, etc., will require special attention before the boric acid treatment can be expected to be efficacious. The next most useful solution in the writer's experience is peroxide of hydrogen (fifteen to twenty volumes strength); this solution is of particular value in tubercular cases.

Of other solutions for syringing, a choice may be made from the following: Carbolic acid in water (two-per-cent); corrosive sublimate solution (1 in 3000–4000); a solution of boric acid in water and alcohol (boric acid 1, distilled water 30, rectified spirits 5); a teaspoonful of ten-per-cent alcoholic solution of salicylic acid to a wineglassful of water; glycerin of carbolic acid and liquor plumbi subacetatis (1 ounce to 10 ounces of water), a dessertspoonful in a wineglassful of warm water.
In the employment of these different solutions a choice must be made according to their antiseptic properties or any injurious microorganisms present, and with reference to the nature of the secretion itself, whether thick and tenacious or thin and watery, and according to the presence or absence of fetor.

Treatment by Strong Rectified Spirit and Strong Astringents.—The use of rectified spirit, first introduced by Weber-Liel, is a method of treatment often of as much service as the boric acid. It is especially indicated when there is much granulation tissue present, and after polypi have been removed.

After cleansing and drying the ear, the head is inclined well over to the opposite side, and from ten to fifteen drops of the warmed solution (usually, to commence with, equal parts of spirit and water) instilled into the ear. The drops are kept in for ten minutes; the solution is then allowed to flow out, the parts are dried, and the canal plugged lightly with salicylic wool. This treatment is repeated two or three times a day, and the strength of the spirit gradually increased until it can be borne pure.

The author frequently uses the spirit drops in combination with a solution of boric acid in water (vide solutions), and finds it often more efficacious than either alone.

If there be much fetor it is well to add a little carbolic (two-per-cent) to the solution. Iodoform may be combined with the alcohol, half a drachm of the powder to an ounce of the spirit.

In very obstinate cases, with extensive destruction of the membrane, excessive granulation tissue, and great swelling of the mucous lining of the middle ear, astringents or caustic applications are indicated. Ten to fifteen drops of a ten-per-cent solution of nitrate of silver are poured into the ear in the same way as the spirit drops, and when allowed to run out again the ear is syringed with a solution of chloride of sodium to neutralize any of the silver salt remaining; or the diseased mucous membrane may be rubbed over with a solution of the strength of forty grains to the ounce.

In a few cases, where there have been no signs of any acute inflammatory mischief, the writer has carefully touched the diseased mucous membrane or granulations with chromic acid fused on a probe, and has obtained good results. It must be very carefully applied as the caustic action of the chromic acid is very great.

The lessening of the discharge is an indication to diminish the frequency of the syringing, and to employ dry applications. The ear is cleansed with cotton wool-wicks and the diseased parts are insufflated with finely powdered boric acid. A powder formed of boric acid four parts and iodoform one part may be substituted for the plain boric acid, particularly in tubercular cases.

In every case of otorrhea it is incumbent on the practitioner to make a thorough examination of these regions. As the author has already stated, the majority of cases of perforative otorrhea originate in some morbid condition present in the nasopharynx, etc., and it is as necessary to treat these morbid conditions as to treat the middle ear itself. Enlarged tonsils, adenoids, hypertrophic rhinitis, spurs, nasal polypi, nasal or postnasal catarrh, must all receive the special treatment appropriate thereto.

It is unwise to remove adenoids or tonsils if there is profuse fetid otorrhea. An attempt must therefore be made to render the middle ear as aseptic as possible, and then the particular operation may with safety be undertaken. For nasal or nasopharyngeal catarrh he orders daily syringing of both nostrils with one of the two following solutions:

3 Sodii chloridi,
Sodii bicarbonatii, ±± grs. viij;
Sodii boracii,
Sacchari albi, ±± grs. xv.

One powder to be dissolved in half a tumblerful of warm water and used with the syringe.

Or

3 Glycerin. acid: carbolicii, ± xij;
Sodii bicarbonatii, grs. vij;
Sodii boracii, grs. vi;
Aq. destill., q. s. ad f3 j.

If syphilis or tubercle be present they must receive appropriate treatment. Good food, fresh dry air (mountain air), good sanitary surroundings, and tonics, especially iron, must be recommended. The patient must be warned against exposing himself to cold draughts, and told to carefully avoid the entry of cold water, especially sea water, into the ear or ears.

It is only by careful attention to all these details that success to any degree is likely to be obtained. The patient or his friends must be told of the possible consequences of the disease, and strongly urged to persevere in the plan of treatment laid down by the surgeon, although it may be a long time before healing takes place.
ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.

McCollom, from an examination of mortuary statistics, both in this country and in Europe, and from a clinical study of 4200 cases of diphtheria, gives the following conclusions in a paper published in the Boston Medical and Surgical Journal:

1. That the death-rate of diphtheria has been reduced to a remarkable degree by the use of antitoxin.
2. That in order to derive full benefit from this agent it is important that it should be given in large doses early in the course of the disease.
3. That antitoxin should be frequently repeated, until the characteristic effect is produced on the diphtheritic membrane.
4. That antitoxin does not cause albuminuria, and that it has no effect in producing heart complications in this disease.
5. That the physician who does not use antitoxin in the treatment of diphtheria fails to do his whole duty to his patient.

THE ANTITOXIN TREATMENT OF TETANUS.

In the Boston Medical and Surgical Journal LUND reaches the following conclusions in regard to this question:

Although the statistics of the antitoxin treatment of tetanus up to the present time apparently show a diminution in the mortality under this treatment, they may be legitimately criticized as on the whole insufficient in total number, in definiteness of reports, and as probably not including all fatal cases treated.

The more carefully we study them the less evidence do we find that the antitoxin treatment, and not the mild course of the disease, was responsible for the favorable course in the cases which have recovered.

There is no satisfactory evidence that harm has resulted from the injections.

There is a distinct probability that in the great majority of the total number of cases treated the dose of antitoxin, especially the all-important initial dose, has been too small to have any possible effect upon the disease.

The treatment in view of the present intractability of the disease demands further trial.

There are certain means by which we can hope to make it more effective, and these include earnest efforts on the part of those engaged in the production of serum to secure a stronger product, and on the part of those who employ it in treatment to give a sufficiently large initial dose, and to give it at the earliest possible moment. The serum should be injected directly into the blood-stream.

The strength of the antitoxic preparations furnished by the Massachusetts and the New York boards of health, when first supplied, was so slight as to render it necessary to employ 500 cubic centimeters as the initial dose.

A valuable field for the use of antitoxin lies in its employment for immunizing purposes.

The treatment of tetanus, according to our present knowledge, should consist of: (a) Thorough disinfection of the primary focus by mechanical means, including, if necessary and practicable, amputation; (b) the thorough local employment of such chemical antiseptics as have been shown to destroy both the bacilli and the toxin; (c) symptomatic treatment by sedatives, etc.; (d) thorough diuresis; (e) intravenous injection at the earliest possible moment of an amount of antitoxic serum which shall contain at least 500 antitoxic units.

HAS THE TREATMENT OF DIABETES MELLITUS IMPROVED?

The recent review of diabetes mellitus at the Massachusetts General Hospital from 1824 to 1898 would at first glance appear to answer this question in the negative, for the statistics show no decrease in mortality during this entire period. But such a conclusion can hardly be drawn, since any marked changes which have been made in the treatment of this affection have been of very recent date. Even the latest works in English, not excepting that by William- son, do them scant justice.

It is, perhaps, as much the change in our point of view of regarding the disease as the variations in treatment which are capable of producing better results. The statement occurs so frequently in text-books that diabetes is incurable, that the practitioner loses all his enthusiasm the moment a patient with this disease presents himself. In despair he attempts a palliative treatment, writes out lists of articles headed "allowed," or "to be avoided," and perhaps adds a recipe for some new diabetic flour; while in giving the prognosis the patient's courage is perceptibly lowered.

In contrast to this gloomy picture is the
hopeful view which is best set forth in Naunyn's treatise. The key-note of this is contained in the following quotation: "That cases apparently severe at the outset, when subjected to a vigorous treatment, take a proportionately favorable course, while others running a severe course are, as a rule, those subjected late or not at all to careful treatment." Coming from so eminent an authority, this statement is of the greatest value, since it counteracts the tone of the usual text-book. Naunyn, in carrying out this idea, says further: "I consider it an unfortunate curtailment of the physician's task in the treatment of diabetes where it is said, 'the essential task of the physician is to support the invalid in an endurable condition of life for a long time.' In the writer's opinion a broader, more definite purpose should be put into the treatment, namely this: the strengthening of the deranged bodily function, or at least the checking of further disintegration of the same." This change of view is our first step toward an improved treatment for diabetes.

That drugs are of little value in this disease is now generally admitted. Notwithstanding this, there are few of us who have not heard from eminent sources that considerable success has been obtained from this or that remedy. Patients like the idea of taking medicine and come to the doctor for the sake of the prescription, just as they often go to church for the music. The advice as to the diet and hygiene, either of the body or soul, forms too commonly an entirely secondary consideration. But this question of drugs, at least for a host of remedies, is definitely settled for us by the Massachusetts General Hospital report above alluded to. The pancreatic preparations proved unsatisfactory. No drug, save opium, commended itself, and that in no wise as a specific. It certainly is another step forward, this relegation of the Pharmacopoeia in diabetes to a very minor position.

Rollo recommended an animal diet as long ago as 1797, and it would seem as if little improvement in treatment had taken place, or could be hoped for in the future, along this line. But the point made by Rollo was the prominence given to an animal diet over carbohydrates. Little was said of the great class of fats, and what was said was quite as much against as for their use; for example, at the Massachusetts General Hospital, as late as the period 1840-1855, occurs a record of the following diet: "Lean meat, with a small quantity of stale, dry, or toasted bread, avoiding all fatty, farinaceous, and saccharine articles." That fifty years ago there was a lack of appreciation of the importance of fats can be understood, but that this idea has been allowed to persist seems incredible. That it does persist can be seen by consulting the most recent books of medicine, or by looking over the proceedings of the meetings of the British Medical Association recently convened in Montreal.

The importance of fats is seen first from the fact that they are the form of food best assimilated by the diabetic patient. Nearly all the sugar and starch given leaves the body unused, and for every 100 grammes of albumen there is the possibility of 45 grammes of sugar appearing in the urine, whereas from fat little, if any, sugar is formed. But this is not all, and herein lies another great advantage in fats. Each gramme of fat is capable of furnishing nine calories on being oxidized by the natural process of the body metabolism, whereas a gramme of proteid matter yields but four calories, even allowing that none of it is converted into sugar. These are facts, and on these facts a rational treatment of diabetes must rest.

In the light of all this, the books still continue to recommend or countenance skim-milk and buttermilk either as a prominent constituent of the diet or as worthy of trial. The difference between the amount of sugar in ordinary milk and these by-products is unessential, but the difference in fat is so great that it amounts to more than one-half of the total quantity of nourishment therein contained. In every liter of good milk the diabetic patient receives some 300 calories more nourishment (and that of the quality best suited to his needs) than he does in skim-milk.

Following the remarks on skim-milk in the text-books comes the section on diabetic breads—that pitfall over which few pass in safety. Over and over again these have been exposed in Boston many years ago, and again this year. Need we wait until the millennium before it is recognized that a small known quantity of ordinary bread is better than an unlimited amount of bread nearly as rich, or even richer, in carbohydrates?

The commonly accepted mode of treatment of diabetics has been, and still is, of a negative character. This is a much more serious charge against it than to say that skim-milk and diabetic breads are used. Article after article is cut off from the patient's diet, and
even what is left him he is only "allowed," until finally he comes to think he eats at all only by sufferance. The secret of the successful dietetic treatment of diabetes lies entirely in the opposite direction. The diet is positive. It is not a question of how little sugar, but rather how much fat. It is not so much the withholding of articles of food as it is the prescribing of those best adapted to the patient's condition. Von Noorden gives, to form a basis of the diet, what he calls his "Eisernen Bestand," which consists of 60 grammes butter, 2 eggs, 10 grammes olive oil, 30 grammes fat cheese, 1 liter milk, and 30 grammes alcohol. This quantity of food can be taken daily, is sure of assimilation, and furnishes the patient some 1600 calories, or nearly two-thirds of all that he needs. For the remaining amount there can be considerable latitude, admitting of variety. That one may rightly prescribe and the other follow the directions given, both doctor and patient must know the amount of food taken, and have a working knowledge of its three constituents. This can only be obtained on the doctor's part by the study of first principles. This does not mean theoretical but practical study. He must know how much butter can be taken at a meal, how much cream can be mixed with the coffee, how much oil can be used in salads, etc. Only by personally weighing and measuring the kind of food his patient is to eat can he rightly advise him. Then, if it is found that the sugar continues to be excreted, the cause can be located, and a more suitable form of carbohydrates given, or the total amount can be further restricted. Really an interested, intelligent cook is of more value to most diabetics than a trained nurse. A Denver doctor recently said of consumptives that if they wished to get cured of phthisis they must make a business of it. In diabetes this applies to doctor and patient alike. Between the two a partnership must be formed, and with a more cheerful way of regarding the disease at the outset, a better appreciation of the value of fats, and a positive diet list, the results will show that there is even in diabetes an improvement in our treatment.—Boston Medical and Surgical Journal.

FORMALDEHYDE GAS AS A DISINFECTANT.

In the Boston Medical and Surgical Journal of October 6, 1898, Brough tells us that he believes we have in formaldehyde the best practical gaseous surface disinfectant known. For dwelling-house disinfection it is unsurpassed. It is easy of application, and does no injury to goods. It is not ideal, its use being limited to surface disinfection. Its penetrative powers under ordinary conditions are so slight as to be almost valueless. Good results are best obtained by using a large body of gas, and having the rooms as tightly sealed as possible. Length of exposure and the influence of temperature are secondary to the amount used.

Under these conditions disinfection may be regarded as complete after the use of formaldehyde.

THE PRESENT STATUS OF OPINION UPON THE USE OF QUININE IN MALARIA.

The Medical Record of January 7, 1899, contains an article with this title by the editor of the Gazette which, while it covers ground already covered by editorials and original articles in early issues of our journal, is perhaps of sufficient interest to be reproduced in this issue. Dr. Hare says:

"The return to this country of large numbers of soldiers affected by malarial disease, and the prospect of colonization of certain tropical countries by citizens of the United States, have naturally caused much interest in malarial fever, and in the estivo-autumnal parasite in particular. Physicians in the North have suddenly developed an extraordinary degree of interest in a subject which their Southern brethren have long considered of vital importance, and in consequence have studied it with considerable zeal, so that many of them have arrived at definite views as to the matter in debate.

"With these introductory remarks I proceed to a friendly criticism of a special article in the Medical News of December 17, 1898, by an anonymous writer. In this article the value of quinine as an antimalarial is discussed, its praises sung, and then the writer sets his spear and proceeds to charge valiantly into the ranks of those who have the temerity to believe that quinine, like every other drug, has limitations as to its usefulness in malarial disease, and that it is given recklessly and in unnecessarily large doses. This writer also states that 'there is in the air a spirit of opposition to the drug which is liable to do a good deal of harm.' If this is true, it is unfortunate, for no one can deny that, so far as the infecting organism is concerned, quinine acts as a specific.
On the other hand, it is certainly a fact that quinine has been shamefully abused in malarial fever, that it is often given in excessive doses and in cases in which its use is contraindicated, and finally, because the practitioner has been led to believe that 'where is malaria there should be quinine,' he has been led to prescribe it without studying the case thoroughly, and therefore has failed to find that its use is sometimes unwise and that the condition is sometimes not really malaria at all.

"The objection to the paper we have quoted is not that it urges confidence in quinine, but that it urges its universal use, with disdain for those who recognize its limitations. Thus that part of the article dealing with hematuria seems to indicate that the writer falls into the category defined by himself for the writer of an editorial in the Journal of the American Medical Association, namely, 'one with but small experience with malaria, or perhaps none,' since in the next sentence he proceeds to tell us that the voices of our Southern medical men, of the medical men of India and of Brazil and Italy, have been as a unit in favor of the universal use of quinine. That this statement is anything but correct is shown by the fact that a very large proportion of these physicians have testified to the opposite effect. Thus, to take up the most recent literature, we find Goldmann and Krauss, the subcommittee on pathology of the committee on malarial hematuria of the Tri-State Medical Association, in a report published in the Memphis Lancet for December, 1898, telling us that they are 'forced to the conclusion that, malarial hematuria once begun, quinine has no place in its therapy;' and again, 'the injudicious administration of quinine is often responsible for a hematuric attack.' In La Presse Medicale of December 3, 1898, Vincent informs us that American statistics demonstrate that the greater number of patients survive that do not receive quinine, and Netter thinks that the absorption of quinine plays an important part in the production of bilious hemoglobinuric fever. In the Therapeutic Gazette for 1897, page 94, Dr. Meek, of Arkansas, protests 'in the name of humanity' against the use of quinine in this affection; and many other references to papers in Southern journals during the last few years could be given, not all against the use of quinine, but the majority at least preaching care in its use and recognizing that it may do harm.

"In this connection it is proper to point out that physicians elsewhere than in America have reached similar views. Karamitsas, a Greek physician, has published in the Bulletin General de Therapeutique an interesting paper dealing with seven cases in which, in the absence of acute malarial manifestations and because of malarial cachexia, quinine produced hematuria whenever it was given; and further, these patients failed to have this symptom in acute attacks, if quinine was withheld, but suffered from bloody urine if it was used. Rizopoulos in Greece and Tomasselli in Italy have also seen cases in which quinine would produce hematuria. In Guadaloupe, Du Chassaing has reported such cases. Other cases have been recorded by Pampoukis and Chomatianos, of Athens, Greece, and also by Carreau.

"In view of these facts, the statement in the article quoted, that Koch 'started' the present reaction against quinine by stating that quinine was given too freely in African malarial fevers, and that it caused 'blackwater fever,' is scarcely correct. Whatever weight his views may have, he certainly did not 'start' the reaction.

"As long ago as 1892 the author of this paper became interested in this important question and made a collective investigation of the views of physicians living in those parts of the United States in which the mortality from malarial infection was greatest, namely, seventy per thousand or over, and reported the results to the Association of American Physicians.

"While the views expressed by my correspondents were very antagonistic, I thought myself justified in stating that quinine is often useless and harmful in the bloody urine of malarial infection, although it was also evident that circumstances might exist in which the drug could be used. Much of the contradiction is more fancied than real, and depends upon the fact that the bloody urine may be due to many causes, such as acute renal congestion in the paroxysms owing to great distention of the renal vessels, to degenerative renal vascular changes as the result of chronic malarial poisoning, because of degenerative processes which cause the red cells to disintegrate, and finally to paroxysmal hemoglobinuria not due to malaria.

"It is evident, therefore, that quinine might be useful in one case with bloody urine and not in another, and the burden of this article is not to prove that quinine is never useful, but that it is not a 'cure-all' in
these states. That it may do damage is proved by the authorities quoted, and by the following facts, which show, I think, that my friend who wrote the editorial in the *Journal of the American Medical Association*, whoever he may be, is not so ignorant as the *Medical News* would have us believe.

"That malarial poisoning does cause nephritis in certain cases is admitted by every one. Thayer tells us that in Baltimore tube-casts were found in the urine of 17.5 per cent of the malarial cases, and Osler says that albuminuria was found in 46.4 per cent of his cases in the wards. If this is true of a point so far north as Baltimore, it probably holds with greater force for those places where the malarial poison is still more virulent. Atkinson has shown that nephritis is a sequel of malarial infection; the committee of the Tri-State Society of Alabama, Tennessee, and Mississippi has found nephritis in all cases of fatal malarial hematuria; Ralfe has done likewise; and Kiener and Kelsch have reported that there is glomerulitis.

"Admitting, then, that malarial disease produces changes in the kidneys, let us see if quinine is capable of so doing. We find that all writers of experience state that quinine, particularly in full doses, possesses distinct irritative effects on the genito-urinary tract, and I have proved that in poisoning by quinine the kidneys become congested and finally inflamed.

"Guyochin has reported cases of genito-urinary irritation after the use of quinine, and Faginoti reports a case in which there were pain in the urinary passages and the discharge of a few drops of blood on urination. Monneret has seen positive hematuria follow its use, and Rivet has observed vesical spasm and hematuria after an ordinary dose of the drug. Dassat reports the development of hematuria, with retention of urine, from cystic irritation due to quinine, and Cachere records two cases in which hematuria followed the use of quinine. In one of these, a boy of thirteen had profuse hematuria after the dose of ten grains, and a girl of seven years was affected similarly whenever quinine was used. Stillé states that quinine irritates the urinary organs, and that if any part of this tract is diseased the lesion is aggravated.

"Three facts may therefore be deducted: (1) That quinine sometimes produces hematuria in malarial disease; (2) that malarial disease often congests, irritates, or inflames the kidney; (3) that quinine is capable of doing likewise.

"This paper so far has, doubtless, seemed destructive to the use of quinine in malarial nephritis and hematuria, but it is not to be regarded as advocating that no quinine be given; rather that it be given wisely. It must be evident that hematuria coming on in acute intermittent malaria is a manifestation of blood-breakdown or renal lesion, and is a result of the congestive stage of the attack. To give quinine during the hematuria is equivalent to 'shutting the door after the horse is stolen,' and in addition gives the kidneys the irritating work of elimination. It would seem more rational to give it to prevent the next paroxysm.

"In hemoglobinuria occurring with the paroxysm there is probably less danger in using quinine than when true hematuria is present, since the kidneys are not as hindered and clogged by blood-clots; but even here it must be evident that quinine can only stop future attacks, not the one already in existence. Should the attack of hemoglobinuria be prolonged, indicating that the malarial poison is destroying the corpuscles independent of the chills, then quinine may be needed. If it is given, I believe that cholagogues, followed by a brisk purge, should be used to aid in the elimination of coloring-matter through the liver and bowel, and to relieve the kidneys of all labor which it is possible to remove. If in any case the intermittent paroxysms are so frequent as to make the quinine necessary, in view of the fact that other measures have failed, the same attention to the bowels should be given; the kidneys should be flushed out by diuretics such as the vegetable salts of potassium, and the quinine be given because the danger of the continued attacks is greater than that of renal involvement from the drug.

"The third class of cases, namely, those which are included under the severe forms of bloody urine associated with jaundice and general hemorrhages from the stomach, the bowels, and the nose, are more difficult to treat than those just discussed. They present all the difficulties which non-hemorrhagic remittents produce, and the peculiar inability on the part of the absorbents, coupled with the bilious vomiting, makes all medication difficult, let alone the complication of bloody urine.

"Much that has been said in regard to the condition of the kidneys and the contraindi-
cations to quinine in the milder forms of malaria, already spoken of, holds true with the severe form of hematuric fevers, yet here the very severity of the infection calls for quinine, although the contraindications are stronger than ever. This may be cleared up, however, by a recollection of three facts, namely: (1) that this malignant form comes on suddenly with the access of a malarial attack in a patient already broken down; (2) as an attack of hematuric jaundice without any evidence of another dose of malarial poison; (3) there are a number of remedies which are capable of doing much good before quinine is resorted to. The quinine will be needed in the cases suffering from active malarial paroxysms imposed on the subacute or chronic forms, but will not be needed in the second class of chronic cases, which should be treated by other measures directed to the relief of the dyscrasia and bloody urine.

"It seems evident, therefore, that quinine, like the tints of the artist, must be ‘mixed with brains’ if the best results are to be obtained, and that its routine use with blissful ignorance of its dangers ought not to be advocated; while on the other hand, no one should for a moment cast discredit upon a truly specific remedy."

---

**SOME PRACTICAL POINTS IN THE TREATMENT OF THE CHRONIC FORMS OF HEART DISEASE DUE TO RHEUMATISM.**

The London *Lancet* of December 10, 1898, contains an article on this topic by ERNEST SANSON, of London. He tells us that often in a patient who presents himself to us after convalescence from an attack of rheumatism it is found there is something wrong with the heart — either morbid enlargement without other signs, or murmurs indicative of incompetence of the mitral or aortic valves. It should be realized as the first practical point that even though weeks and months may have elapsed since the obvious symptoms of rheumatism, it is most probable that the rheumatic disease is and about the heart is not absolutely quiescent. Slowly and without betrayal by symptoms the changes go on in the endocardium and the fibrous structures of the valve and its neighborhood. If things go well a mere thickening results, the valve curtains remaining competent; if adversely, there is contraction of the firm and thick tissue, degenerative changes supervene, and the valve becomes incompetent. But this may not be all; there may be waves of retrogression alternating with improvement, successive storms of disease with enlargements and shrinkings of the heart.

The first practical point urged by Dr. Sansom in regard to treatment is that we should realize that the problem is not the simply stational one of restoring a lack of power in the heart muscle, but a dynamical one of overcoming the influences of various factors and varying phases of disease. Take, first, the medicinal treatment. There are signs of some cardiac failure, and the question arises, shall we prescribe digitalis in some form? Many of us have had most favorable experiences of the usefulness of the drug. Suppose that the patient who has come to us has given evidence of the difficulty of breathing, of effort, of some pretilial pitting, or more marked signs of edema of the lower extremities have appeared, and possibly of basic edema of the lungs. Digitalis is given in the form of tincture, infusion, or powder, and after a few days, perhaps even though complete rest has not been enforced, there is vast improvement—the output from the kidneys has been increased, the diuresis has cleared away the dropsy, and after some days of further treatment the adverse symptoms vanish.

But the experience of a second case may be very different. Administration of the drug fairly in increasing doses during five or six days is followed by no sign of amendment. Perhaps there is evidence of intolerance in vomiting, of diarrhea, of signs of faintness, of irregularity of the rhythm of the heart; or that without any such signs the drug disagrees—it is simply inert. The pulse is not rendered slow, the tone of the artery does not improve, diuresis does not result, and the dropsy persists or increases. How are we to interpret the facts? Sansom thinks they may be briefly elucidated thus: If there be no rheumatic febrile disturbance, and if the heart tissues are not undergoing active inflammatory changes, digitalis properly administered acts well. If there be waves of active inflammatory action, circumstances not always to be readily discovered, digitalis fails. Such has been Dr. Sansom’s experience. In a paper founded on precise investigation by Dr. Lauder Brunton and Dr. Theodore Cash the authors thus express themselves: “The administration of digitalis, or of drugs which act like it, to patients in a febrile condition is likely to have much less
effect on the pulse than at the normal temperature, and if the temperature be very high they may have no effect at all while this persists. When the temperature begins to fall the pulse naturally becomes slower, and this slowness is increased if digitalis has been given at the height of the fever. It is therefore evident that digitalis and its congeners, if they are given at all when the temperature is high, should be given with great care, for otherwise the medical man may be induced by the apparent inaction of the remedy to push its administration too far during the fever, with the consequence of producing too great depression of the pulse during defervescence." Dr. Sansom supplements this by expressing his own opinion that not only during periods of rheumatic pyrexia, but also when the heart structures are actively infiltrated during rheumatism, though it may be in the apparently chronic stages, digitalis is often inert or harmful.

If two, or perhaps three, days have passed without improvement the drug should be omitted and the patient advised to take perfect rest in bed. Of course, the withholding of the digitalis should be earlier if signs of intolerance arise. Now comes the question of counter-irritations or topical applications to the precordia. Small blisters may be applied after the manner recommended by Dr. Caton, of Liverpool—one of the size of a half-crown near the heart's apex, and when the consequent irritation is subsiding a second blister of similar size close to it, and others following. Or these small blisters may be placed over the intercostal spaces. In France the thermodiery (pointes de feu) is most frequently employed. Though these methods may tend to relieve subjective symptoms, Dr. Sansom has not been convinced that they have any decided therapeutic effect. He thinks that there has been much more decided evidence of amendment from the topical application of the ice-bag as recommended in pericarditis by Dr. D. B. Lees. An ice-bag suspended from a cradle should rest lightly over the heart region, a thin layer of flannel intervening. The ice-bag may be applied for periods of half an hour and removed for like periods. Usually the patient is made comfortable by these means and the heart tumult is allayed. A temporary dilatation of the heart may under such treatment subside in two or three days. A small hypodermic injection of morphine acetate or morphine hydrochlorate, from one-tenth to one-fourth grain, is a great aid to the calming and comforting of the patient. Dr. Sansom says he thoroughly indorses Dr. Clifford Albutt's commendation of this therapeutic plan, which he himself introduced in heart cases. "By the mouth opium is behind other sedatives in value, its use being attended by grave drawbacks, but hypodermically, in doses beginning at one-tenth of a grain and gradually ascending to a quarter of a grain if necessary, it is a precious means of relief. The physicians who still protest against its use are unfamiliar with the practice. There is no remedy which calls forth so warm a tribute from the patient himself." From these considerations the second practical point he insists upon is that any sign of rheumatic storm in the heart—a state of things occurring in an apparently chronic phase and obscurely indicated by symptoms—should be treated by placing the patient at rest in bed.

Sansom thinks it his duty to utter a warning note against the indiscriminate use by the non-medical public of methods of muscular exercise. In many cases of organic heart disease in their truly chronic stages these methods of increasing the physiological activity of the heart muscle are of very high value, but there is much danger in the case of the rheumatic heart even though the disease may seem to be chronic. If there be the rheumatically swollen heart—a condition of which the patient himself may be unconscious—the use of muscular exercises should be prohibited. To advise these would be equivalent to a direction to a patient with inflamed joints to run. After a period of such absolute rest exercise should be commenced gradually, for too long inactivity is of course harmful, but the question of the duration of the period of complete rest should be left to the medical adviser.

Can medicines aid the absorption of the effusions in and about the heart in the seemingly chronic stages of rheumatism? Sansom thinks it is generally agreed now that salicin and the salicylates have no directly favorable influence. Indirectly ministering as they undoubtedly do to the comfort and well-being in the acute stages and when the joints are painful, they are inert as regards any heart inflammation. He says he has some lingering affection for the old alkaline plan of treatment in the more chronic stages. He prescribes alkalies with no idea of neutralizing any morbid acid, but simply because he thinks they soften membranes, increase osmosis, and thus facilitate the work of the
lymphatics. Another plan of treatment which he believes to be of great value is the administration of small doses (one-half grain) of calomel three times a day for periods of three or four days together. In many cases he has seen what has seemed to him an extraordinary improvement under such plan of treatment.

After the systematic use of the ice-bag has been omitted it seems to be useful to apply iodine in some form over the integument of the præcordia. Painting the surface with liniment or tincture of iodine is a well known procedure. The method which he adopts of inunction of an ointment of iodide of ammonium is, he thinks, much to be preferred. A drachm of iodide of ammonium is to be intimately mixed with an ounce of benzoated lard. The ointment is rubbed into the skin over the heart region by means of a piece of flannel or a pledget of cotton-wool for two or three minutes night and morning. After the rubbing a piece of cotton-wool, flannel, or light tissue is to be kept over the surface. This ointment does not stain the skin like iodine preparations, and it causes little or no irritation, though it readily permeates. He thinks it much to be preferred to our old friend the belladonna plaster, and certainly preferable to the sticky, messy, dirty perforated abominations which some of our patients delight to disfigure themselves with. Moreover, there is no interference with the daily ablutions or affusions with sea-water, which are so generally beneficial.

**ANIMAL VS. VEGETABLE FERMENTS.**

Austin contributes the results of a series of experiments on this topic to the *Boston Medical and Surgical Journal* of December 3, 1898. He finds that taka-diastase possesses a greater power of converting starches, in proportion to its weight, than does saliva or pancreatin, though perhaps the test was not fair to saliva, as the amount, one cubic centimeter, was arbitrarily taken as an equivalent to one-tenth gramme pancreatin and taka-diastase; since, however, only 5½ parts per thousand of saliva are solid, 5.5 milligrammes are compared with 100 milligrammes. All of these digestants are practically nullified in an acidity equivalent to that of gastric juice, so that practically no digestion can take place in the stomach from any of these digestants.

These digestants are not destroyed by the acidity of the gastric juice, and there is no practical reason why their activity should not go on after they have passed into the intestines and alkalinity is reestablished.

Taka-diastase apparently carries the process of amylaceous digestion a step farther than the other two, forming dextrose instead of maltose. In how far this is of value he thinks we cannot say until we know more about the condition attending the secretion of succus entericus, which contains the major part of the invertin, and whether it is ever absent.

**CONSTIPATION AND ITS MODERN TREATMENT.**

Herschell in the *Clinical Journal* of November 30, 1898, states that he is afraid that the rising generation of medical men are in danger of losing much of that finesse which enabled our forefathers with but a limited selection of drugs to adapt them as perfectly as they did to the circumstances of the case. The art of prescription writing for a perfect laxative pill—a pill whose action should be at once pleasant and adequate—is almost a lost one. There was generally a reason for each ingredient in their time-honored formula. Take, for example, the pilula aloes et myrrhae of the British Pharmacopoeia. How many young practitioners could tell offhand the utility of the gum-resin? And in consequence, because they cannot see the use of it (practical therapeutics having been relegated to a very secondary place in their scheme of education), they rarely prescribe it. And yet, as a matter of fact, it is of extreme value, and gives to the pill its characteristic action—that of a laxative without a tendency to be followed by subsequent constipation. It was found by clinical experience that the addition of a resin, devoid of active purgative properties, prevented to a great extent reaction in the direction of constipation by possibly acting as a tonic to the mucous membrane, and so the pil. aloes et myrrhae came into being. In the treatment of chronic constipation drugs are of extreme use, but to make them reliable tools we must thoroughly understand how they act and what we are going to do with them. The medicinal substances which we shall find advantageous to use may be arranged in the following groups:

1. Those which excite peristalsis. Of these we have nux vomica and Calabar bean.
2. Those which relieve spasm. In this group we find belladonna, the bromides, valerian, and perhaps asafetida.
3. Drugs which increase the secretions of the gastrointestinal tract. The most useful of these are chloride of ammonium and phosphate of soda.

4. Medicines having a beneficial effect on the neurasthenic condition — valerianate of zinc, nitrate of silver, ergot, arsenic, and the glycerophosphates of soda. The glycerophosphate of lime must be avoided, as it has a distinctly constipating effect.

5. Laxatives. These are never to be used except in special circumstances.

With these few drugs at our command we are in a position to very materially assist the action of the other means which we are using. If there is enterospasm we shall give belladonna or one of the bromides. If the peristalsis is defective, nux vomica will be found useful. When the stools are dry and hard we shall employ with great advantage drachm doses of phosphate of soda in combination with a bitter, and perhaps taraxacum; or we shall take advantage of the undoubted properties of chloride of ammonium in increasing the intestinal secretions. We owe not a little of the knowledge which we possess as to the action of the latter drug to the valuable researches of Lockhart Gillespie. In addition to its action upon the intestinal tract it appears to have the remarkable power of removing any dyspeptic symptoms which may be present. This is probably due to its action in increasing the amount of hydrochloric acid in the gastric secretion.

But the question will probably now be asked, how are we to secure adequate actions of the bowels during the course of the treatment?

From the first we must make up our minds to abandon the use of purgatives. We must procure the necessary actions:

1. By the use of a small daily enema of cold water. Whilst enema of hot water distinctly relax the intestinal tissues, cold water acts as a tonic, and may be used with practical impunity. At first we may give a small injection every day, and as by degrees the intestines take on their normal function it will be required less frequently until we can dispense with it altogether. For slight cases this will be sufficient.

2. The oil enema. This has been already alluded to in the paragraph upon removing the contents of an impacted rectum. But it has even a more important use as a means of procuring a daily action of the bowels, and should be immediately resorted to in cases which resist the simple enema of cold water. For these cases the best way of administering it is by means of an ordinary glass funnel. A long colon tube is passed up into the bowel about twelve inches, and is connected by a short length of tubing to the funnel in question. The patient is lying on his side in bed with the pelvis elevated a few inches. The physician, standing by his side, holds the funnel with the left hand a foot or so above the patient, while with the right he slowly pours into it the oil, which has been previously warmed. The oil should be introduced into the bowel very slowly, at least fifteen minutes being taken up in doing so. About ten ounces will be sufficient for an adult, and two or three for a child, according to age. The oil should then be retained as long as possible, and if the injection be given at bedtime the action of the bowels will often not take place until the following morning. The effect of one injection will usually last for several days, and often for a week, the patient having a daily stool during that period. When the effect passes off another should be given. In any case where it is desirable to procure the maximum effects these injections may be given every day. It sometimes happens that in certain cases the oil will be found to produce an unexpected purgative effect. In these cases there is probably some increased peristaltic action which hurries unduly the bile and pancreatic juice along the intestines, and these, coming in contact with the oil, form irritating soaps. It is advisable when using oil enemata to now and then administer a large alkaline douche.

THE PHYSIOLOGICAL ACTION OF CACTUS GRANDIFLORUS.

In the Revue de Thérapeutique of October 28, 1898, Anitimoff has recorded in a St. Petersburg thesis twenty-seven experiments which he has made upon dogs. He finds that in the dose of 0.2 to each kilogramme of the animal cactus causes a marked slowing of heart and an increase of the blood-pressure. This slowing is due to the influence exercised by the cactus upon the inhibitory centers of the heart, and the rise of arterial pressure is due to its action upon the vasomotor center in the medulla and also to stimulation of the nervomuscular fibers in the peripheral blood-vessels. In human beings he found that the prescription of fluid extract of cactus in the dose of three to ten drops three or four times
a day slowed the pulse in the majority of cases, but in other instances produced no modification in its rate. It increased blood-pressure and increased diuresis. Under its influence in cardiac disease dyspnea and cough were diminished. He does not think that the drug is capable of producing cumulative effect, but believes that it is particularly indicated in functional troubles of the heart, as, for instance, in Graves' disease and in nervous palpitation.

THE TREATMENT OF ASTHMA.

The Revue de Thérapeutique Médico-Chirurgical quotes Von Noorden as having stated that atropine in ascending doses is the best treatment of asthma of spasmodic type. The treatment should be continued for from four to six weeks. In his hands the method consists in administering $\frac{1}{30}$ of a grain of atropine every two or three days, and then gradually increasing the dose until it reaches as much as $\frac{1}{15}$ or $\frac{1}{10}$ grain, after which the dose may again be decreased. It is necessary that the patient should be continually under the observation of the physician to avoid accidents under this method of treatment, but with care accidents are not met with.

THE VALUE OF PHOSPHORUS IN RICKETS.

A number of years ago Wegner (Journal de Médecine de Paris, Oct. 16, 1898) described the changes which are produced in the bones of animals by the ingestion of phosphorus, and for this reason supposed that it would prove a valuable remedy in the treatment of rickets. Kassowitz, who applied this theory to the treatment of infantile rickets, obtained excellent results and stated that in the dose of one-fiftieth of a grain a day the symptoms of rickets rapidly disappeared. On the other hand these statements have been contradicted by other observers. Baginsky, of Berlin, has employed phosphorus to combat rickets and observed eight cases out of seventy-two which presented slight amelioration.

Leray observed twenty-five cases, amongst which seven seemed to be benefited, while in the remaining eighteen the results obtained from the administration of phosphorus were doubtful or of no value.

Weiss, of Prague, in seven cases, obtained only one positive result. On the other hand, Swetchen has observed forty-one cases with four cures, twenty-four improvements, and the balance were not benefited. In other words, it is evident that phosphorus is not by any means a specific in this condition, but that it may be employed as an adjuvant to other treatment.

In the Revue de Thérapeutique Médico-Chirurgical of November 1, 1898, Lop, of Marseilles, makes a report upon the influence of rest upon rickets and upon its treatment by phosphorus. The formula which he employs, according to the method of Kassowitz, consists in:

- $\frac{1}{3}$ Phosphorus, 1-20 grain;
- Lipanin, 1 ounce;
- Powdered sugar and powdered gum arabic, of each $\frac{1}{6}$ ounce;
- Distilled water, 1¾ ounces.

A small teaspoonful of this represents about one milligramme of phosphorus. In certain cases in which the digestive apparatus is in good condition Lop administered in addition and as a vehicle for the phosphorus cod-liver oil. He ordered two grains of phosphorus dissolved in a quart of the oil, and then gave small doses of the mixture—one or two teaspoonsfuls. Should there be any evidences of gastrointestinal or other derangement produced by the phosphorus treatment, it is temporarily stopped for from four to twelve days. The patients which he treated, for a sufficient length of time to gain any definite knowledge concerning them, ranged in age from eighteen months to four and a half years. Their rachitic symptoms were marked, being cranial tabes, large bellies, dilatation of the stomach, diarrhea, defective dentition, and incomplete growth.

In a large proportion of the cases good results were not obtained until after the treatment had been maintained for a good many months. Seven of his patients presented very marked improvement after eighteen to twenty months of treatment. Five others showed moderate symptoms of improvement after ten months, and one of his patients died of linteric diarrhea.

THE TREATMENT OF ANEURISMS OF THE AORTA BY HYPODERMIC INJECTIONS OF SERUM GELATIN.

Huchard reports upon this treatment in La Presse Médicale of October 26, 1898, and states that he has obtained relative cures in aneurismal tumors after twelve injections. He also cites the case of Boinet, who has
obtained unfavorable results, and a second case in which no results have been obtained by Barth. In the case of Boinet the first injection did not favor the deposition of the clot in the proper portion of the aneurism, with the result that there was contraction of the pulmonary artery followed by pulmonary tuberculosis and death. In the case of Barth the patient, a woman of forty-nine years, had an aneurism of the ascending portion of the aorta. Under the use of iodide of potassium no beneficial results occurred, and after the injections of gelatin had been made three times in one week fever developed, and after five injections (though diminution was observed in the tumor) the temperature rose still higher and a large abscess developed. The patient had symptoms of dyspnea, which became more and more severe, and death finally ensued. At the autopsy an aneurism was found occupying the ascending portion of the arch of the aorta. Coagulation had taken place in a considerable portion of the sac and also extended in the left subclavicular artery. On the other hand, there is no doubt that these injections sometimes aid in the coagulation of blood in aneurismal tumors.

Apropos of this a report made by Lance-reaux to the Paris Academy of Medicine, October, 1898, is of interest. He described five patients with aneurism of the arch of the aorta, who were treated by subcutaneous injections of a solution of gelatin. This solution was composed of thirty grains of gelatin in three ounces of normal saline solution,.6 of one per cent. It was injected under the skin of the buttock and deep into the subcutaneous tissues in the dose of three ounces, and these injections were repeated at different intervals varying from two to twelve days; ten, fifteen, or twenty injections usually sufficed to produce a complete cure. In the discussion which followed his paper, Huchard confirmed the statement that these injections give good results, and stated that they are to be employed to combat otherwise hopeless aneurisms of large size, and further, that the injections cause little inconvenience, although they are somewhat painful. He also quoted a case of hemoptysis described by Rasmussan in which similar injections had been made for the purpose of controlling hemorrhage, with good results. The only danger in this treatment seemed to be the possibility that the clot while forming might in part be swept off into the general circulation.

THE USE OF CANNABIS INDICA AS A LOCAL ANESTHETIC.

The Journal de Médecine de Paris of October 30, 1898, states that Arousan has employed cannabis indica with good effect as a local anesthetic to relieve dental pain. The tincture is diluted three to five parts with alcohol, and is introduced into the cavity of the tooth by means of a tampon of cotton. These tampons are also placed about the gum below the tooth. This author asserts that in the course of a few minutes a considerable degree of anesthesia is produced. If the alcohol is too strong the tincture may be diluted by means of hot water.

[Personally, we doubt whether cannabis indica possesses much local anesthetic power. —Ed.]

THE VALUE OF METHYLENE BLUE IN THE TREATMENT OF NEPHRITIS OF A HEMORRHAGIC TYPE

Netchaef (Journal de Médecine de Paris, Oct. 16, 1898) has written of the value of methylene blue in the treatment of nephritis of a hemorrhagic type. Seven cases of nephritis were treated by Lemoyne by methylene blue; three recovered and four were much benefited. He quotes Dehio and Einhorn as having written favorably of the influence of methylene blue in this affection, and Kramer is stated to have administered this drug in four cases in the dose of two grains given three times a day. Under its influence it is claimed that the blood disappears from the urine, the albumen is greatly diminished, and the patient’s general condition is much improved.

THE DANGER IN THALLIUM ACETATE.

During the past year or two a number of the French journals have contained articles describing the value of thallium acetate for the purpose of controlling night sweats in tuberculosis. It will be remembered that the dose which was used was 1½ to 3 grains, which was given an hour before the expected sweat, and that often a single dose produced the desired result, although sometimes it had to be repeated. There seems to be no doubt that thallium acetate possesses this power, but, on the other hand, it is worthy of note that it is capable of producing alopecia, which in one case recently reported by Huchard was so well developed that complete baldness followed the use of a number of doses.—Journal de Médecine de Paris, Oct. 16, 1898.
THE TREATMENT OF RINGWORM OF THE HEAD.

In *Treatment* of October 27, 1898, Aldersmith writes on this subject. He thinks that the first duty of the medical attendant is to most carefully examine the whole scalp, and to mark out all the diseased places if the extent is not sufficient to warrant shaving the head. If there be only one or a few places, it is infinitely better to mark them by cutting the hair from them, and for one-third of an inch round them. It is useless for a medical man simply to write a prescription, and to tell the mother to look over the head and apply an ointment to the places; but he ought to find all the places, or order the scalp to be shaved, and give most minute and definite instructions to the mother or the nurse.

If the patches are extensive, and over most of the scalp, shaving or close clipping is advisable; but it is well to leave a small fringe round the scalp, so that it may appear under a cap. Tinea, as a rule, does not invade the edges of the scalp, and a fringe can generally be left.

The second point to remember is—especially if there be only one or a few patches—that the spread of the disease ought to be stopped at once. Many cases are allowed to spread from one or two small places over most of the scalp from forgetting to use a parasiticide over the entire scalp. It is essential to treat the whole scalp, even if only one place can be detected. Therefore, after the places have been marked, the head should be thoroughly washed with Jeyes’ or carbolic soap, and, after drying, a lotion or ointment should be well applied. Sulphur (precipitated) is the best thing to use for this purpose, mixed with salicylic acid or white precipitate:

1. Sulphur, precip., 3 j., ad 3 iss; Acidi salicyl. gr. xv, ad gr. xx; Adip. benz., q. s. ad 3 j. M. ft. unguent.

2. Sulphur, precip., 2 j., ad 3 iss; Hydrarg. ammon., gr. x, ad gr. xv; Creasoti, 1/4, ad 1/4, xxv; Adip. benz., q. s. ad 3 j. M. ft. unguent.

3. Sulphur, precip., 3 j., ad 7 iss; Glycerina, 1/4, xx; Spirit. rect., 3 ij; Acidi salicyl. gr. v, ad gr. xv; Aquae, q. s. ad 3 j. M. ft. lotio.

A lotion or ointment should be used to the scalp every night, and ringworm very rarely spreads if either of the above have been properly applied; but of course other small places, which were just commencing and not seen at the first examination, may be found during the next fortnight, and must be marked and treated. When all spread has ceased, carbolic glycerin (1 in 8) is very useful to apply to the rest of the head.

If the places be few, it is far better to mark them out, and to use some strong lotion or ointment to them, than to shave the head and treat the whole scalp with the same ointment. If a boy, it is better to have the rest of the hair cut moderately close (half to one inch); if a girl, it is quite possible to cure ringworm without cutting the rest of the hair, but most careful examinations must be made from time to time to see that every place is under treatment.

In a short article it is impossible to describe all the treatments for ringworm, or even to fully describe many, with all the notes about isolation, prevention of spread to other children, the use of caps, and the proper way to apply ointments and lotions; and reference may be made to where the author has more fully described them.

One of the last remedies advised is formal. The writer never uses it now, and believes it to be extremely painful, and often productive of scars. Croton oil, if properly applied, is far safer to use, and much less painful. Personally, he usually cures small places of tinea by inflaming them with croton oil, and refers to this treatment later on.

The usual parasiticides employed are as follows:

Goa powder (chrysarobin) may be rubbed into the places with water or lemon juice, or used in an ointment or lotion; but it should not be employed for extensive forms of the disease, and is rarely successful in chronic cases. The following combination is useful:

B Chrysarobini (Kemp & Co.), gr. xx, ad gr. xl; Acidi salicyl., gr. xx, ad 3 j; Olei amygdalorum, 3 ij; Adipis laevis hydrosae (lanolin), q. s. ad 3 j. M. ft. unguent.

Sulphur may also be added. Directions should be given to have the ointment well rubbed into the places for at least ten minutes at a time, twice a day. Precautions must be taken to prevent the ointment getting over the rest of the scalp, or on to the face. Chrysarobin dissolved in benzol or chloroform may also be used to small places; and elsewhere he has described its use.

Coster’s paste:
REPORTS ON THERAPEUTIC PROGRESS.

B Iod, 3 ij.;
Ol. picis liquid., ad 3 j.
M.

This is very useful for small places, and should be applied till a scab forms; then this must be picked off, and the paste again applied, till all the diseased stumps are removed.

Cresote may be used with turpentine, or iodine. A mixture of cresote and iodide of sulphur is good—twenty to forty grains in one ounce of cresote or a mixture of cresote (two parts) and turpentine (six parts).

Iodide of mercury is an excellent parasiticide for small places.

B Hydarg. iodi rubri, gr. iv, ad gr. vij;
Sodii iodi, 3 ss;
Spirit. chlorof., 3 ij, ad 3 iv;
Aque, ad 3 j.
M. ft. lot.

This must be well soaked in, but must not be strong enough to produce scabbing, and ought only to be employed for small places.

Perchloride of mercury he never employs; it is inferior to the red iodide, and more likely to cause poisoning if used too strong.

Salicylic acid is a safe and excellent parasiticide, and one frequently advised. A good formula is:

B Acid. salicyl., gr. x, ad gr. xxx;
Etheria, 1 ij;
Spirit. vini rectificati, q. s. ad 3 j.
M. ft. lot.

This may be soaked into the places, and had better be used only ten grains to the ounce at first, and then increased. It may also be dissolved in chloroform and ether for small places, as this dissolves the fat, dehydrates the hairs, and often causes them to come out.

Salicylic acid can be freely used in ointments (twenty grains to one drachm) combined with precipitated sulphur (1/2 to 3/2 drachms), and is most useful for extensive forms of the disease, and in young children.

Sulphur is one of the best applications, and may be used as above, or with white precipitate.

B Sulphur. praecl., 2 iss, ad 3 ijs;
Hydarg. ammon., gr. xv, ad gr. xxx;
Acid. salicyl., gr. 20, ad 3 j;
Oleü amyg., 1 ij;
Lanolin, q. s. ad 3 j.
M. ft. ung., or it can be mixed with benzoated lard.

Oil of turpentine can be used with iodide of sulphur and cresote. Some speak highly of first washing the scalp in hot water, then soaking with turpentine, and, while still wet, applying tincture of iodine; but this treat-

ment, like most others, often fails in completely curing ringworm.

The essential point in treatment is to persevere with the lotion or ointment for some time, and not to continually change the application, for it must take two or three months to get out all the diseased stumps, and for the new hair to grow. Only perseverance and great care in finding and marking all the places will insure success.

AN EXPECTORANT MIXTURE.

The *Journal de Médecine de Paris* of October 30, 1898, states that the following formula is a useful one for the purpose of facilitating expectoration:

B Apomorphine hydrochlorate. 2 grains;
Dilute hydrochloric acid, 20 minims;
Simple syrup, 2 ounces;
Distilled water, 6 ounces.

For an adult one, two, or three teaspoonsfuls of this mixture may be taken every two or four hours, or a small teaspoonful may be given to a child, equally frequently. The idea is to give enough to cause the expectorant effect without nausea and vomiting.

A CLINICAL CONSIDERATION OF THE USE OF THE IODIDES IN CHRONIC PARENCHYMATOUS, AND OF CREOSOTE IN SUPPURATIVE, NEPHRITIS.

Under this interesting title Weber writes in the *Post-Graduate* for October, 1898. He tells us that after sufficient clinical observations of the good influence of small doses of the iodides in certain forms of chronic nephritis during the last eighteen years, and the value of cresote in the medical treatment of inoperable surgical kidney in the past six years, he believes he is justified in drawing the following conclusions:

The iodides given in relatively small doses, three or four times daily, and continued for many months and even years, have the power to retard, modify, and improve subacute and chronic inflammatory processes concerning the connective tissue of parenchymatous organs like the kidneys, the liver, the lungs, and particularly the sclerotic disease of the arterial vessels.

It appears that this salutary effect is brought about by direct inhibition of the proliferation of the connective tissue, as well as by subsequent induction of disintegration and fatty metamorphosis of infiltrated corpusscular elements and the removal of the same.
It is reasonable to hold that the drug manifests and develops its activity through the lymph channels and spaces of the affected organs by direct action upon the irritating substances, by stimulating the vasomotor nerves and increasing the functional activity of the parts.

The favorable influence of the iodides can be clinically demonstrated, and is more decided in arterial sclerosis than in similar disease of parenchymatous organs, and will show itself frequently, whether the underlying cause is gout, alcoholism, or syphilis. In cases with a syphilitic history, however, it is well to give larger doses of the iodides for a while—i.e., from ten to fifteen grains, three times a day.

Creosote in doses from two to four to six grains, three times a day, steadily administered, he recommends as a safe and trustworthy remedy in supplicative disease of the urinary organs. Guaiacol carbonate in similar doses will do as well, and may be used when creosote is not borne by the stomach.

He has found them to reduce suppuration and fever considerably, improve nutrition, and help the patient greatly in cases which had passed the limits of surgical interference.

Professor Ramon Gutierrez, in discussing Weber's remarks, said that the paper just presented was scientific as well as practical, and had the merit of presenting observations extending over a very long time. He had had very little experience with the iodides in chronic parenchymatous nephritis. Many of the old cases of Bright's disease seen by him at the City Hospital had improved very decidedly under the use of iodides, but he had ascribed it to a syphilitic element in them. A number of excellent authorities made the statement that the iodides were useful in all cases of Bright's disease. Senator, of Berlin, was one of the clinicians making this assertion. He states that it seems to act beneficially whether or not arterial sclerosis is present, and that it probably acts directly on the blood-vessels, on the inflammation itself, or upon the blood-pressure in the kidneys.

Referring to suppurative nephritis, or rather to pyelonephritis, dependent upon tuberculosis of the kidney, he said that the two drugs which had seemed to him to work best were creosote and guaiacol. Both of these seemed to have an antibacillary action, or at least seemed to limit the production of or neutralize the effects of the toxins produced by the tubercle bacilli. Under this benign influence the lesion in the kidney improved. In treating tuberculosis of the prostate, seminal vesicles, and bladder, he had obtained good results from creosote.

THE TREATMENT OF DISEASES OF THE STOMACH.

The British Medical Journal of October 29, 1898, contains the opening address on this topic delivered by Herschell at the recent meeting of the British Medical Association. He thinks that the agents which are generally useful in the treatment of diseases of the stomach are: Electricity in its different forms; massage and mechanical therapeutics, such as movements, vibration; hydrotherapeutics, both as a means of improving the general health, and as a local treatment to the stomach in the form of lavage, spray, or douche; local treatment to the stomach by the gyromele of Turck. To these, he thinks, we must add drugs when used not for their influence upon the chemical processes of the stomach, but when administered for their tonic action on the muscular or nervous tissues of the body respectively.

First of all, as regards electricity: The author takes this first because it is a particularly happy example of a method of treatment with respect to which there is a difference of opinion. On the one hand, we have the evidence of many medical men of the greatest reliability who habitually use it in the treatment of atony of the stomach and allied conditions; and, on the other hand, we have a number of records of experiments made in the physiological laboratory where the operator could not succeed in producing contraction of the muscular substance of the stomach, whether the electricity was applied by the use of external electrodes or directly to the mucous membrane of the stomach. Hemmeter alone has apparently succeeded in demonstrating by his intragastric bag, fitted with double electrodes, that contraction of the stomach could be produced with electricity, but only with such a strong current that it would probably prove hurtful to the individual.

We have also on this side of the question a statement of Prof. Clifford Allbutt, who says: "Electricity may be found useful some day in atonic cases, but as yet I have seen no definite good from its use, whether internal or external; other physicians seem to have been more fortunate." A statement like this in a book which claims to be an authoritative
exposition of current medical views is much to be deplored; it must infallibly prevent many men from paying that attention to this valuable agent which it deserves. It also shows us how very important to the progress of medical science are exchanges of individual experience. Any one who will study the current literature of the treatment of diseases of the digestive organs must come to the conclusion that the clinical evidence in favor of the beneficial effects of electricity in atonic conditions of the gastrointestinal tract is overwhelming.

But all the laboratory experiments quoted must not be taken as conclusive. Many of the earlier ones were performed by medical men without that special experience of vivisection and the methods of the biological laboratory which alone can insure the absence of fallacies. And in this respect they unfortunately resemble a good deal of the so-called research work of the present day, which floods our journals with a host of crude theories and ill-digested facts. It is possible to reconcile this conflicting evidence if we assume that galvanism probably produces its undoubted good effects by acting not directly upon the muscular substance but upon the nerve supply of the stomach and intestines.

Having held this view for many years, Herschell has been in the habit of treating cases of atony of the stomach mainly by the application of the continuous current to the solar plexus and to the ganglia of the sympathetic and vagi of the neck. The application is made in the following manner: The patient is placed upon his back upon a couch, and the negative electrode applied to the nape of the neck, the anode being placed upon the epigastric region. Both electrodes are flat, flannel-covered plates, having each an area of twelve square inches, and remaining stationary during the application, which consists of from three to fifteen milliamperes passed for from five to ten minutes. The electrode is then removed from the nape of the neck, the rheophore attached to a three-inch disk electrode, the epigastric plate remaining in position. The current is then reversed, and the disk applied for one or two minutes in succession to each of the ganglia of the sympathetic in the neck, a current strength of one or two milliamperes only being employed.

This is a part of Herschell's routine method of treating atony of the stomach, and he has had no reason to complain of its want of efficacy. He very rarely uses the intragas-

tric application of electricity, convinced as he is that it is not the application of galvanism to the ends of the nerves in the stomach that helps the patient, but the galvanization of the ganglia from which these nerves proceed.

Herschell took this opportunity of drawing attention to a special form of electric application which he has recently found to be very useful in the treatment of atony of the bowel and constipation. It is a primary coil, such as is constructed for giving faradic baths, and not only is wound with very thick wire, but is capable of giving very slow interruptions. It appears to really set up peristaltic action in the intestines. He has on several occasions seen its application cause an immediate stool. It also acts quite as efficiently as massage and muscular exercises in restoring tone to the abdominal muscles. In using it he places an indifferent electrode on the buttocks, and applies the other pole with a roller electrode over the abdominal muscles and over the intestines, following the curve of the colon, using interruptions of from 120 to 200 per minute. It has also given good results in cases of atony of the stomach.

The next agent which comes before our notice is massage and its congeners, gymnastic and other mechanical means.

Massage of the stomach is a mode of treatment which has its advocates and its opponents. Against it we have von Ziemssen and Rosenheim, whilst in its favor are, among others, Professors Ewald, Boas, Riegel, Zabludowsky, and Sieri. According to Hemmeter, it may be used:

1. On an empty stomach before breakfast to strengthen the muscular power of the stomach.
2. Three or four hours after a meal to assist in the expulsion of chyme, or to mechanically mix its contents.

According to the same author, it may be usefully employed:

1. In disturbance of the motor function depending on atony of the walls.
2. In stenosis of moderate degree.
3. In chronic gastritis with reduced secretion.
4. In gastroptosis.
5. In certain cases of nervous inhibition of the peristaltic movements.

Vibration of the stomach is a mode of treatment to which Herschell has paid a good deal of attention, and which he will describe in detail in a paper which he hopes to have an opportunity of reading shortly. Gymnastic exercises for strengthening the abdominal
muscles are chiefly useful in the treatment of gastroptosis.

In the treatment of the atony of the stomach, Herschell has on many occasions seen much benefit derived from douching the stomach alternately with hot and cold water. Although this can be done with the ordinary stomach-tube and funnel, it is much more convenient to make use of an apparatus which provides for the return of the liquid introduced into the stomach, and allows the lavage to be a continuous process. The best arrangement for this purpose is undoubtedly Turck's double-current stomach-tube, but an efficient substitute can be made by cementing together side by side two ordinary red-rubber stomach-tubes, one to conduct the fluid into the stomach, and the other to take it out again. It is a very important point to bear in mind that the afferent tube must be of smaller caliber than the efferent one, otherwise the risk is run of overdistending the stomach. In my own practice I connect the afferent tube with two separate reservoirs containing respectively water at 100° F. and cold water, by means of the two-way tap used by hair-dressers for shampooing. By this means one can effect the gradual change of the hot to the cold douche, and vice versa. Herschell usually gives a séance of ten minutes' duration, changing the temperature of the water every sixty seconds.

Professor Turck, of Chicago, has devised a very valuable improvement in the apparatus, by providing the end of the afferent tube with a bulbous extremity perforated with minute holes. By this means an intragastric spray is produced.

Under the head of dietetics we have several clinical problems of great interest. The first of these is the proper diet to be given to cases where the secretion of hydrochloric acid is in excess. We are here confronted with the following dilemma: A diet of proteids would theoretically appear to be indicated, since:

1. Meat and other albuminous substances are readily dissolved by the hydrochloric acid.

2. These articles of diet will combine to a greater extent with, and hold in combination more of, the free hydrochloric acid, thus diminishing gastric pain and irritation.

3. The diastatic action of the saliva will be inhibited almost as soon as starchy food reaches the stomach, instead of continuing for half an hour or so as in the normal stomach, and experiments have shown that this cannot again be perfectly revived in the alkaline duodenum. Therefore starch food must be almost useless to the organism.

Yet, if we put a patient on such a diet of proteids, although we bind a large quantity of free acid, we may possibly encourage its hypersecretion by the law that Nature when able responds to the demands made upon her. The continued call for hydrochloric acid to combine with and deal with the albuminous material upon which we are feeding the patient will certainly tend to hypertrophy the glandular elements of the gastric mucosa, and the last state of the stomach will be worse than the first. It is, therefore, more than probable, theoretically, that hyperchylia will be perpetuated by a proteid diet. The alternative will consist in the administration of a carbohydrate diet partially dextrinized, at the same time neutralizing the greater part of the hyperacidity of the stomach by large doses of alkalies.

The second great problem in practical dietetics is the subject of the administration of predigested foods, and with it may be profitably discussed the use of pepsin, pancreatin, and other digestive ferments. According to present ideas, it is quite superfluous to give peptonized albumins as long as the motor power of the stomach is normal, and as long as we are certain that duodenal digestion is unimpaired. Even when the power of the stomach of emptying itself into the duodenum has been lost, as in cases of pyloric stenosis, we shall probably be wasting our time in converting the food into peptone, since the investigations of Cahn have demonstrated that in these cases no peptone is absorbed from the stomach. In his own practice Herschell agrees with Hemmeter in confining the use of peptone and albumose to cases where the ordinary diet is found to be insufficient to preserve the nitrogenous equilibrium of the body.

Herschell does not think that pepsin by the mouth is ever indicated, nor can he conceive of any circumstance where it can do good, except as a local application to the gastric mucous membrane. In nearly all cases where pepsinogen is really absent, there is also such deficiency of hydrochloric acid that a sufficient quantity of the latter could not be given by the mouth to digest even a small meat meal when conjoined with the pepsin administered.

Pancreatin can only be given with advantage in the exceedingly rare cases where there is a complete absence of hydrochloric
acid in the stomach, as it is completely destroyed by normal gastric juice. But in these cases it is probably a doubtful benefit, since in order that the pancreatic digestion may take place in the stomach, we must provide an alkali such as bicarbonate of soda; and as the acidity of the gastric juice is undoubtedly one of the chief stimulants to the pancreatic and duodenal secretions, we may be very seriously affecting the digestion in the small intestines.

An important exception is to be found, however, in the taka-diastase. Professor Ewald has pointed out to us that deficiency in the amount of salivary ferments is a matter of extreme rarity, but circumstances not infrequently combine to prevent it from carrying out its work. It may be that by imperfect mastication, or owing to defective teeth, the flow of a proper amount of saliva is not excited, but by far the most frequent obstacle is the presence of an abnormal amount of hydrochloric acid in the stomach, such as we get in ulcer, hyperchlorhydria, and some other conditions. This, as we have already pointed out, inhibits the action of the salivary ferment, and consequently in these cases there will be indigestion of the starchy part of the food. By the administration of taka-diastase and alkalies we are enabled to give these patients a diet containing a large proportion of carbohydrates if we wish to do so.

---

THE TREATMENT OF MOTOR DEFICIENCIES OF THE STOMACH.

In the British Medical Journal of October 29, 1898, Ewald of Berlin tells us that the only internal remedy for motor conditions at our command is strychnine. We can do something mechanically for the food stagnation in the stomach and for the muscular atony by lavage, stomach douches, and massage vibration and electricity. Where these remedies fail, nothing is left but gastroenterostomy, switching, so to speak, the stomach out of the digestive tract to a great extent. Ewald especially warns us under these circumstances against the too long continuance and too frequent employment of washing out of the stomach. Where lavage does good, it does so very soon; where it does no good, patients easily suffer in their general nutrition, and this may go on to symptoms of inanition, from the continued removal of a certain amount of material intended for nutrition.

A last point that we have to consider are the neuroses of the stomach, those dyspeptic, colic-like symptoms in the region of the stomach which are caused by a disturbance of the nervous apparatus of either local or central character, and only secondarily proceed from an affection of the glandular or muscle mechanism; this last being often of so slight a character that it completely escapes our diagnostic methods. Here may be classed nervous dyspepsia, nervous hyperemia of the stomach, the anomalies of secretion that rest on a nervous basis (hyperchlorhydria and hypochlorhydria), nervous vomiting and nervous crises (crises gastriques). The last, however, are mostly, though not always, caused by an affection of the central nervous system.

In these cases the treatment of the gastric condition, in so far as it is not purely symptomatic, consists in the treatment of the central nervous system. In neurotic cases the affection of the nervous system must be treated by general tonic and constitutional treatment. Only after this comes the question of treating the dyspeptic symptoms, though they seem to stand out so prominently. Here, indeed, it is often necessary, after one is sure of the good condition of the gastric functions, to prescribe a comparatively hearty and plenteous diet, despite the patient's objections to it. An example of this method of treatment is the "rest cure," as introduced by Weir Mitchell. It is, however, not sufficient in many cases. Ewald has often had patients in whom he succeeded in a short time in bringing about a considerable addition to their weight, but the dyspeptic symptoms remained unchanged. In such cases the gain in weight is not due to increase of muscle substance, but to a deposit of fat and to retention of water in the tissues. Only after such patients have had a thorough course of roborant treatment in the mountains or on the seacoast, or in a well situated sanatorium for dietetic and hydrotherapeutic treatment, does real improvement set in.

So much on the general principles that must be borne in mind in the treatment of stomach diseases. Ewald selects certain special features of the treatment of these conditions.

One of the most satisfactory affections to treat is ulcer of the stomach, provided, of course, that it be not too old, and that the ulcerative process has not already given rise to cicatricial contractions and adhesions. Way back in the thirties the treatment of ulcer of the stomach recommended by certain Eng-
lish authorities was the withdrawal, as far as possible, of all food by the mouth. Recently this so-called rest cure has become identified with the name of V. Leube. Since we have found that the nutrition of the organism, even though only for a limited time, may be carried out by nutritive enemata, we have been able to go a step farther with this treatment. Ewald treats patients in whom he suspects an ulcer of the stomach as follows:

The patient is confined absolutely to bed, and for the first five or six days receives as nourishment only nutritive enemata, which are given in the usual way three to four times a day. The thirst is combated by small ice pellets, the feeling of hunger by a few drops of a cocaine solution. It is remarkable, however, how slight these sensations are as a rule.

If the pains continue at the beginning, a small morphine injection in the stomach region gives the best results. As a rule this is not necessary, as the pains cease spontaneously as soon as the mechanical irritation of the ulcer stops. This point constitutes an excellent differential diagnostic symptom for nervous cardialgia and biliary colic, which often are deceitfully like ulcer of the stomach in their symptoms. Nervous gastric pains will by the withdrawal of food be not at all, or only for the moment, influenced—that is, so long as the suggestive effect of the novelty of the treatment continues.

After no food has been given by the stomach for three to five days, according to the subjective symptoms of the patient and the general condition, then a few test spoonfuls of some easily absorbable material are given. The simplest is a thin milk gruel of some meal or other—wheat, or oats, or mandarin, or one of the many artificial preparations. If this causes no pain, the next day more is given. After three or four days other easily digestible substances are added, but at first in a more or less liquid form. Then the consistency of the foodstuffs is increased and the nutritive enemata become fewer in number.

After the first trial, however, should pain occur, then exclusive feeding by the rectum must be resumed, and in some cases it may be kept up for ten to fourteen days. We cannot hope in such cases, however, to retain our patients in nutritional equilibrium for so long a time. A considerable loss of weight ensues, and Ewald has found by careful observations of organic metabolism that the body loses a considerable amount of nitrogen. This loss is, however, of little importance and is soon made up for, and the original body weight far outstripped when the patient is able to eat plentifully without pain.

This method of treatment should be carried out wherever it is possible. It gives such excellent and sure results that one can say that where it fails there must be complications present—old cicatrices, especially at the pylorus, perigastric adhesions—or else that some other affection, whose seat is perhaps not in the stomach at all, must be the cause of the pains.

Of the other methods of treatment—bismuth, argentum nitricum, iodine, iodide of potassium, orthoform, and so on—he says nothing.

The good results of the method described above occur, it is true, only in recent cases; older cases, with deeply burrowing ulcers, with prominent thickening of their edges, with stenosis of the pylorus, or other contractions, the hour-glass form and the like, can only be permanently relieved by operative measures, though the setting the stomach at rest causes passing relief from pain. It is, of course, understood when surgical relief is sought that the conditions must be favorable—that is, that the ulcer must be situated where the surgeon can get at it and treat any sequelae that may result from its excision.

As to the indications for surgical interference, they were discussed at the last Surgical Congress in Berlin. Ewald's own experience justifies him in accepting Leube's indications in this matter; they are as follows:

In gastric hemorrhage, if the bleeding continues or occurs repeatedly and resists treatment.

When internal medication fails to relieve severe pain, and persistent vomiting and inanition are setting in.

In perigastritis and abscess in the neighborhood of the stomach (subphrenic abscess).

In perforation into the abdominal cavity as soon as the patient is able to stand the operation.

There are a series of successful operations for perforated gastric ulcers in the literature. Out of six cases of gastroenterostomy operated on by Ewald's advice for ulcer of the stomach and its consequences (stenosis of the pylorus, hour-glass stomach, perigastritis), only one died, a mortality of 16.6 per cent; in cases of gastrectomy for ulcer also but one death, a mortality of 14.3 per cent. Meanwhile, it must not be forgotten that any
operation upon the stomach is a serious one, and that a number of favorable circumstances must not combine in order to assure successful results. Especially in bleeding from the stomach is the question of operative interference hard to decide, and the selection of the time for it difficult. On the one hand, even severe hemorrhage may cease suddenly; on the other, the finding of the bleeding vessel in the stomach is often extremely difficult and requires specially favorable conditions. In desperate cases of gastric hemorrhage, in which ordinary internal remedies such as ergot, morphine, chlorides of iron, etc., do no good, Ewald has often seen prompt cessation of the bleeding after lavage of the stomach with ice water. This not only removes the decomposing irritant blood-clots that have gathered, but has a direct contractile effect upon the blood-vessels and favors thrombus formation. It is best to carry out the lavage after previous cocainization or after a small injection of morphine, so as to forestall tendency to vomit.

Out of the large chapter of neuroses of the stomach Ewald selects but one group—nervous gastrosuccorrhea, nervous gastric hypersecretion. It has nothing to do with the hyperchlorhidria of gastric ulcer, or with the stagnation of superacid stomach contents in atonic processes or in stenosis of the pylorus, though it is often confused with these. There is question in it of a stomach not increased in size, at a time when digestion is not in progress, especially during the night, secreting an excessive amount of gastric juice. This gastric juice may be normal, or contain too much HCl, but it is always, and this is what is characteristic of it, free from stagnation products—that is, from remains more or less of preceding meals. There is found in such cases in the stomachs of fasting patients a clear or but slightly cloudy fluid, of considerable amount, which has all the properties of normal gastric juice. This fluid irritates the gastric mucous membrane and causes severe pain, which at times wakes the patients from sleep. These pains diminish or disappear if the patient takes food, and so neutralizes the acidity of the secretion. After awhile these pains recur, and so have a certain similarity with the pains in ulcer of the stomach, from which, however, they may be differentiated by the fact that they occur at a time when the stomach is normally empty. Patients get the idea that the affection may be cured by a rigid dietary; they eat little, they sleep badly, other nervous symptoms set in, and they run down in health. Should the diagnosis of ulcer of the stomach be made the treatment Ewald has described above will of course be unsuccessful. The diagnosis can be made with assurance from the finding of a large amount of normal gastric juice in a fasting stomach, when, at the same time, all symptoms that point to stenosis or dilatation of the stomach or to gastric ulcer are absent.

The treatment of this condition is, like that of all neuroses, twofold: First, tonic and hygienic regulations for the general condition, hydrotherapy and climatotherapy. Secondly, symptomatic treatment of the stomach. The ordinary so-called sedatives—the bromides, zinc, belladonna, codeine, morphine, hyoscyamus—are all of no use, Ewald asserts from a vast personal experience. His best results have come from regular evacuation of the fasting stomach, and a spraying immediately afterwards of the gastric mucous membrane with a half-per cent solution of AgNO₃. Whether we accomplish this spraying by simply allowing the solution to flow in, or by means of the stomach douche or Einhorn's stomach spray, is a matter of indifference. During the day he gives the patient every two hours a teaspoonful of a five-per-cent solution of potassium iodide and bicarbonate of sodium, and allows only rectal alimentation, in order to avoid all irritation of the gastric mucous membrane. Even this method is not always successful, and does not guarantee against relapses, but it is the most efficient in his experience.

One of the most serious of the neuroses is hysterical vomiting. Cases occur in which for weeks every attempt to nourish the patient fails. Every bit of solid or liquid food will be immediately vomited, and rectal enemata, despite the addition of opium, will be at once ejected, or if retained do not serve in the least to make the stomach more tolerant of food. The patients get worse and worse; they emaciate to skeletons, and are unable to hold themselves upright. The condition seems to depend on a cramp of the pylorus, and nothing remains but to do a gastroenterostomy. Ewald has had the operation done in one case recently. The stomach seemed to external appearances perfectly normal. The success of the operation was excellent; vomiting ceased immediately thereafter, and the patient, a woman of twenty-three, gained five pounds in weight in the subsequent three weeks.
The Therapeutic Gazette.

But the diagnosis is not always so easy, nor the success so assured, as in this case. In a similar case of vomiting and pain in the practice of a colleague, the diagnosis, because of a falsely constructed Roentgen photograph, was set down as cancer. Ewald disagreed with this opinion. There was no tumor palpable, no cancer cachexia, no glandular enlargements to be found, while there was an excess of free HCl. He preferred to think that the forty-years-old female patient was suffering from an old ulcer, with adhesion. As the pain was severe and strength rapidly being exhausted, the patient begged to be operated upon. The laparotomy showed nothing abnormal in the stomach, and the organ was not opened; there were no pathological changes around it. After the operation the patient was for a time free from all symptoms, but after a while they recurred, and permitted them to make with assurance the diagnosis of a neurosis, especially as in the meantime certain unmistakable hysterical stigmata had developed.

In conclusion, Ewald said a few words as regards the success of surgery of the stomach in the matter of malignant disease of the organ.

The surgery of the stomach was taken up very hopefully, because of the confidence inspired by the improvement in surgical technique. It was hoped that if the operation were undertaken early the chances of success would be greatly increased, and so great stress was laid on such diagnostic methods as it was thought would make very early operation possible. It seemed for a time, according to Boas's investigations, that the presence of lactic acid would furnish the desired criterion, but the hopes thus raised were rudely shattered. Lactic acid is as little specifically characteristic of cancer as the absence of HCl. That in many cases of gastric cancer lactic acid was to be found in the contents of the stomach was known to Ewald and others long before Boas's publication, but they were more prudent in drawing their conclusions. Nevertheless, Boas has the merit of being the first to lay emphasis upon this fact. The formation of lactic acid is a chemical process that takes place whenever defective HCl secretion and stagnation of the stomach contents occur. This is frequently the case in gastric cancer, but may occur in other affections. Lactic acid only occurs in cases of cancer of the stomach after serious alterations of digestion have set in, and usually a palpable tumor is present.

At present, then, quite as much as ever before, the demonstration of a tumor of the stomach, its position, its size, and its movability, are the indications for operation. If we operate more and earlier now than before, it is, as Ewald showed last year at the International Medical Congress in Moscow, not so much because our methods of diagnosis are more refined and allow of earlier diagnosis, but because of confidence in our technique we make up our minds for operation much earlier than before.

At Moscow Ewald gave the statistics of cases operated on in his hospital from 1894 to 1897—two and a half years. There were 25 gastroenterostomies with 16 deaths (64 per cent); 12 resections with 9 deaths (75 per cent); 22 gastrostomies with 12 deaths (54.5 per cent). In the last year there have been twenty more cases—11 gastroenterostomies, 5 resections, and 4 gastrostomies. Mortality respectively 64.7 per cent, 62 per cent, and 50 per cent.

In six cases after the opening of the abdomen the operation was abandoned because of extensive cancerous degeneration of the stomach and its neighborhood, although only such cases are referred to the surgeon as after careful investigation promise to give favorable conditions and results.

On the whole the results were better in women than in men, and cancers that had developed from ulcers were found more favorable for operation than others. One reason for this, certainly in Germany at least, is that among women there is very seldom an abuse of spirituous liquors; and a second reason is that cancer developed on the basis of an ulcer does not give rise so soon to the cancer cachexia as idiopathic carcinomat. In other words, there is a possibility of radical cure in about twenty-five to at most thirty per cent, and of palliative successful measures in about fifty per cent, of the cases that after careful investigation the doctor considers suitable for operation. This not very encouraging state of affairs is due to the nature of the affection, and cannot be laid at the surgeon's door.

In Ewald's opinion surgical technique has at present practically reached its limit, and its marvelous success in the treatment of non-malignant neoplasms is the best proof of this. If we have no better results to report, then it is due to the nature of things. The impossibility of diagnosing cancer early enough, its tendency at times to diffuse involvement of a large amount of tissue, the
insidious toxic effects of its metabolism upon the organism by which the patient's resistant vitality for operative procedures is notably lessened—all these combine to set limits to the supremest surgical skill.

**ERGOT IN CHRONIC MALARIA.**

**Jacobi,** of New York, thus concludes a paper on this topic in the *Medical News* of October 22, 1898:

There are cases of chronic intermittent fevers with large tumefaction of the spleen that, after having resisted the action of quinine, arsenic, methylene blue, eucalyptus, and piperin, are benefited by ergot.

When enlargement of the spleen is not old and not firmly established the contracting effect of ergot is noticed within a reasonable time.

The attack will disappear before the diminution in the size of the spleen is very marked.

Though temperatures after the employment of ergot remain irregular and now and then somewhat elevated, chills, as a rule, are not noticed with this elevation.

Plasmodia do not seem to disappear from the blood so rapidly as they do after quinine, when the latter is effective. But even while some are still present, the attacks being more or less under control, the patient will feel better.

Complicating local pain requires additional treatment with ice, or cold douches, or heat; chronic hyperplasia demands iodide of potassium or iodide of iron. Digestive disorders may indicate, as they often do, when quinine is expected to act, before the employment of ergot, an emetic, or a purgative, or stomachics.

An experience extending over forty years, in which he has used ergot in many instances, justifies the writer in asserting at least this much: that there are many cases of chronic malaria, apparently intractable, that will get well with ergot.

There are cases, occasionally, in which the return of elevations of temperature after the successful use of ergot makes the combination of ergot and quinine, or ergot and arsenic, advisable, though quinine and arsenic had not been successful previously.

Ergot, like quinine, probably by its sudden contracting effect on the spleen, and by the forcing of large quantities of plasmodia-laden blood into the circulation, is, in chronic malaria when hydremia and spleen tumor are excessive, capable of bringing on the very first attack of chills and fever.

Recent cases of malaria have got better or were improved under the extensive use of ergot, but many resisted a long time; that is why acute cases should rather be treated with quinine.

**THE PHARMACOLOGIC ASSAY OF THE HEART TONICS.**

In a recent issue of the *Journal of the American Medical Association* **Houghton** writes a suggestive paper on this most important topic. It is unnecessary for him to call attention to the great therapeutic importance of the heart tonics, since digitalis, strophanthus, and others of the group are not universally employed by physicians in their daily practice. It is his purpose to point out some of the dangers attending the administration of these drugs, and to offer some suggestions in regard to the selection of the crude drugs and the processes of their manufacture, in order that the danger may be as far as possible circumscribed.

We are not generally accustomed to think of the heart tonics as being the most poisonous remedies employed in therapeutics; yet it is true. According to some of the best authorities the maximum dose of extract of digitalis is about one-half as great as the maximum dose of extract of belladonna; while strophanthin, the active principle of strophanthus, is three times as poisonous as atropine, ten times as poisonous as strychnine, and twelve times as poisonous as absolute hydrocyanic acid.

It would be considered dangerous pharmaceutical practice to allow preparations containing atropine, strychnine, or hydrocyanic acid to be sold, without first being subjected to careful chemical assay and standardization. The United States and other pharmacopoeias give elaborate methods for the exact quantitative determination of these constituents; while owing to the fact that the contained active principles of the heart tonics are glucosides, so easily decomposed by chemical manipulation that an assay cannot be made, no directions whatever are given for the determination of the physiologically active principles of the galenical preparations, and the tests for the purity of the respective glucosides are of little value. Crude digitalis, strophanthus, etc., may be mixed to a greater or less extent with foreign material or inferior drugs when they come into the hands of the pharmacist or manufacturing chemist. By careful botanic
examination the adulterating substance can be detected, and the advisability of garbling or rejecting the lot will depend upon the extent of the impurities. Comparatively little difficulty is experienced in obtaining supplies of digitalis suitable for manufacturing purposes, since this drug is collected in civilized countries. With strophanthus seeds, however, which are imported from savage Africa, much difficulty is experienced.

In order to keep the length of this paper within reasonable limits the writer speaks mainly of the latter drug, its active constituent, strophanthin, and its pharmaceutical preparations. These will serve as types showing the proposed method of assay. About thirty varieties of strophanthus have been discovered. It is claimed that only six of these varieties contain strophanthin, while a few contain the still more active glucoside, ouabain. Holmes, of London, claims that some of the strophanthus found on the British market contains the seed of other plants. In America, however, the crude drug generally consists of a mixture in varying proportions of *Strophanthus Kombe* and *Strophanthus hispidus*. Opinions vary greatly regarding these, some authorities claiming that they are distinct species, while others believe they are merely varieties of the same thing. Preference is generally given to *Strophanthus Kombe*, since it contains about 0.95 per cent strophanthin, while *Strophanthus hispidus* contains only about two-thirds as much. The amount of contained strophanthin is partly dependent upon climatic conditions. It is a well known fact that the physiological activity of digitalis leaves varies within wide limits from year to year.

Strophanthin, having the formula C_{81}H_{48}O_{18} (Arnaud), is believed to be the only active constituent of *Strophanthus hispidus* and *Strophanthus Kombe*. Some investigators, however, claim that strophanthinid also is found. Fraser and others oppose this view, believing that strophanthinid is merely a decomposition product of strophanthin. Strophanthin, like other glucosides, is easily decomposed by acids. It is readily soluble in water and alcohol, but almost insoluble in ether and chloroform. Pure or impure strophanthin, or pharmaceutical preparations containing the glucoside, when brought in contact with sulphuric acid, a trace of ferric chloride being present, yield a bright green color. This reaction is not conclusive, however, since ouabain cannot be recognized in the presence of strophanthin. Holmes, who has given this point much attention, claims that only by purchasing the seeds in the follicle and testing a seed from each follicle can a reliable preparation of strophanthus be made. An assay based on the amount of extractive contained in a given tincture of strophanthus, or other preparations of the heart tonics, is of little value to the physician, since the extractives consist largely of chlorophyll and other inert substances.

After a careful consideration of the difficulties preventing a chemical assay of the heart tonics, and of the great importance to the medical profession of some means of standardizing them, Houghton decided to experiment on living animals, believing that data might be obtained whereby the physiologic activity of the crude drug, its pharmaceutical preparations, and active constituents might be ascertained. Since it could not be taken for granted that every sample of strophanthus seeds or digitalis found on the market was active, it seemed best to adopt methods for determining, first of all, whether the specific action of the heart tonics was manifested by the sample of drug; and secondly, to find methods for standardizing them.

Very extensive pharmacological researches have shown that the several heart tonics act in much the same manner, differing mainly in degree, upon the factors concerned in the maintenance of the circulation of the blood. The most important phenomena observed are slowing and strengthening of the heartbeats and increased blood-pressure. The writer believes only two series of experiments are necessary in order to show whether a given sample of drug possesses the specific action desired, viz., the application of a solution of the crude drug or active constituent to the laid-bare frog's heart, noting the slowed rhythm, the less and less perfect diastole, increased systole, and finally, systolic standstill of the ventricle; and the intravenous injection of such solutions into dogs or rabbits, observing the variations in blood-pressure and heart-beats, as shown by graphic tracings recorded on the kymograph. Other reactions might be obtained in addition, but are not necessary. The physiological activity of each sample of drug examined should be compared with a standard sample of known strength.

A quantitative estimate by pharmacological methods of the activity of the heart tonics is a much more difficult problem than is a qualitative assay. Many series of experi-
ments were necessary in order to decide what methods were best suited for this work. Too great variation was exhibited in the results obtained from blood-pressure experiments on dogs, rabbits, etc., and such experiments are, moreover, quite complicated and difficult to carry out. The writer found that fairly accurate data could be obtained from the application of a solution containing strophanthin, digitalin, etc., to the laid-bare frog's heart, comparing the action of the drug thus tested with that of a sample of known strength. This method, however, was finally abandoned for a simpler one, which gives much better results. It seemed to him quite probable that the strength of the heart tonics could be determined from their killing power when administered to the lower animals. Accordingly, rabbits, guinea-pigs, rats, frogs, etc., were employed for determining the minimum fatal dose of the drug. He finally chose frogs as being best adapted for this purpose. Different species of frogs vary considerably in reaction to the poisons, but the same species behave much alike. He has found it best to employ frogs of a nearly uniform size for the standardization of any particular tonic. Since it is impossible to obtain on the market frogs of exactly the same size, it is best when one has a large number of samples to standardize to have the frogs separated into lots by weight, those in each lot not varying over three grammes; then he can use those weighing 10 to 13 grammes for strophanthin, those weighing 14 to 17 grammes for tincture strophanthus, those of 18 to 21 grammes for tincture digitalis, etc. Frogs weighing less than 30 grammes can be obtained at a very reasonable price from fishermen, as they are too small for the table. However, it is necessary that from the moment of capture they be handled with great care and kept in wet moss, etc., until they arrive at the laboratory, when they should be at once transferred to suitable ponds.

The method of administering the poisons and observing results may be briefly stated as follows: Dissolve the strophanthin, or tincture of strophanthus, in normal saline solution. The strength of the medicated solution should be such that the total quantity to be injected shall not exceed 0.5 cubic centimeter. The fluid should be measured by means of very slender pipettes, graduated into hundredths, into round-bottomed capsules of about one cubic centimeter capacity, from which the last drop may be taken up in a narrow pipette having a long slender point, and the injection then made through the frog's mouth into the abdominal lymph sac. Great care should be taken not to puncture the skin, as this will allow a portion of the injected fluid to leak out. After injection the frogs should be placed in wide-mouthed frog glasses, the plates containing about a quarter of an inch of water. It will be necessary to inject several series of about five frogs each for each sample of the drug to be assayed, a first series to be injected with drug of known standard strength. After testing a large number of tinctures of strophanthus Houghton found that 0.00015 cubic centimeters per gramme body weight represented fairly well the toxic activities of an average sample of tincture prepared from Strophanthus Kombe.

The minimum fatal dose of tincture of strophanthus prepared from various lots of drug obtained from the American market was found to be as follows:

<table>
<thead>
<tr>
<th>Lot</th>
<th>.00015</th>
<th>.00025</th>
<th>.00033</th>
</tr>

</tbody>
</table>

The several tinctures were prepared by one process and with the same menstruum.

The second series are to be injected with doses varying considerably in size. The third series are to be injected after the approximate dose of poison has been found from the second series. From the third series we may almost surely fix the minimum dose. A fourth series should finally be injected, which will fix the limits of strength very closely. The minimum fatal dose should kill at least three frogs out of five. If a less number die it is best to inject another series with doses one point greater.

One very important advantage of the method above outlined for the assay of the heart tonics is the fact that various kinds and sizes of frogs may be employed at any season of the year, the only essential being that at the time the assay is made the standard and unstandardized preparations should be tested at the same time, the frogs being of exactly the same species and kept under exactly the same conditions, comparative results only being necessary, since the standard solution maintains its activity almost entirely unimpaired, as shown by tables III A and III B.

A standard tincture of strophanthus retains its strength very well, as shown by the follow:
ing tests, made on the first standard tincture the writer employed:

Table III A. Minimum fatal dose.

July 6, 1897 .................................................. 0.00015
Oct. 19, 1897 ........................................ 0.00015-
Dec. 23, 1897 ........................................ 0.00015
Feb. 23, 1898 .......................................... 0.00015-
April 25, 1898 ........................................ 0.00015

The loss in strength was so little in nearly one year that it came within the limits of error. Similar results are observed in regard to the permanence of a concentrated tincture of strophanthus.

Table III B. Minimum fatal dose.

July 28, 1897 ........................................... 0.000037
Nov. 10, 1897 ......................................... 0.000037

The ease with which we may always keep on hand a standard preparation of the heart tonics greatly facilitates the carrying out of the test and the accuracy of the results as compared with those obtainable with diphtheria toxin or antitoxin, both of which latter lose their active properties in a comparatively short time.

Table IV. Minimum fatal dose.

Strophanthin No. 1 ................................ 0.000009
Strophanthin No. 2 ................................ 0.000001
Strophanthin No. 3 ................................ 0.000001
Strophanthin No. 4 ................................ 0.00000002
Strophanthin No. 5 ................................ 0.00000001
Strophanthin No. 6 ................................ 0.00000001

The foregoing table shows the variation in the strength of different samples of strophanthin which were obtained from three of the best manufacturing chemists in the world. They were supposed to be pure strophanthin, yet one sample is ninety times as strong as another, the others varying between these limits. The digitalins also vary greatly in strength, but much less than strophanthin. Both strophanthin and digitalin are given daily in tablet or pill form, the amount of active ingredients being ascertained by weight. A splendid opportunity is thus provided for a sudden termination of a favorably progressing heart disease, should the patient be obliged to have his prescription refilled from a fresh bottle. The only way that such remedies can be taken with any degree of safety is to have them prepared from a stock of known physiological strength. Houghton does not dwell upon this subject too long, but desires to say in conclusion that the method of assay herein described is put forth in the hope that others will experiment along this line. He does not claim it is the best method of pharmacological assay that may be devised for this group of therapeutic agents, since he has not yet satisfied himself that it is applicable to every one of the members of the group, but he does claim that some method of assay should be employed.

The use of saline enemas in typhoid fever.

The Lehigh Valley Medical Magazine for December, 1898, contains an article by Walker, from which he thinks the following statements may be drawn:

1. For the relief of the constipation and abdominal distention of typhoid fever, the daily saline enema is the most generally useful measure that we have.

2. The irritative diarrhea present in some cases is greatly benefited by a daily enema.

3. The effect of the ulcerative process is good, and the likelihood of hemorrhage diminished by promoting cleanliness of the intestinal tract.

4. Cases receiving a daily enema are less likely to develop serious nervous symptoms.

5. The daily enema insures a certain amount of the saline solution being absorbed, thereby relieving thirst, improving the circulation, and encouraging urinary excretion.

6. In cases of stubborn hyperpyrexia the cool enema may assist in controlling temperature.

7. In relieving restlessness and promoting the comfort of the patient, the enema often acts very happily.

Varix: Its Causes and Treatment, with Special Reference to Thrombosis.

In The Lancet of October 15, 1898, Bennett publishes a valuable address entitled as above. For practical purposes, so far as their causation is concerned, varicose veins may be divided into four classes: (1) those which are congenital; (2) those due to obstruction of blood-current; (3) those caused by strain without thrombosis (traumatic); and (4) those the result of thrombosis.

The congenital cases form a large percentage of those usually met with and consist of two varieties: (a) those connected with the subcutaneous veins only, and (b) those having a direct and gross communication with the deep venous trunks. The second of these varieties is by far the more important.

As an example of the first variety, the local mass of varix often seen in the calf of the leg may be mentioned, and of the second
kind the convoluted collection of varicose veins about the inner side of the knee, which, turning toward the middle of the popliteal region, ends in a large vessel which joins the deep vein directly by passing through the normal opening in the fascia over the popliteal space.

A third variety of congenital varix is that in which the whole venous apparatus of a limb is overdeveloped, with or without corresponding increase in size of the main artery. Such cases vary in degree from what is nothing more than a little exaggeration in the size of the vessels to a morbid condition which may, without inaccuracy, be termed diffused naevus. Congenital varix is sometimes very extensive.

There is no doubt that the veins of persons who when young are subjected to abnormal and especially sudden strain, such as may occur in hard "training," in gymnastics, particularly the lifting of heavy weights, or in any violent exercise, as, for example, heavy football playing, tend to become varicose more than the veins of persons whose occupations or amusements throw less strain upon the vascular apparatus. In proportion to the strength of the individual the greater will be the tendency to the development of varicosity. The immediate cause in cases of this kind is the giving way of the vein valves, usually the proximal pair, which under condition of great general tension naturally have to bear the greatest pressure, although they are not infrequently imperfect anatomically.

The effect of thrombosis of the large venous trunks, such, for example, as the iliac vein or inferior vena cava, especially as a complication of enteric fever, in the production of general varicosity of the limb below, is too familiar to call for comment. The importance, however, of thrombosis as a factor in the causation of a certain type of varicosity in the leg is not commonly recognized, nor is Bennett aware of any mention of the matter in surgical literature.

Strains and other similar injuries of the leg or ankle followed by pain and acute tenderness down the middle of the calf, sometimes insufficient to cause more than momentary or very transient trouble, but at times enough to render the limb practically useless for a considerable period, are not infrequently followed very soon by dilatation of the saphena veins, which, if more than very temporary, passes subsequently onwards to tortuososity, with the development of characteristic varix which rarely extends above the knee, terminating generally at the point at which the great saphena of the thigh is completed by the junction of the two trunks at the upper end of the leg. The cause of this development is thrombosis of the main deep veins—i.e., the veins comites of the posterior tibial artery, etc. The primary saphenal dilatation is merely the result of the establishment of the collateral circulation. If the thrombosis clears up, or if the unaffected deep veins take up the collateral function, this dilatation is temporary only and soon disappears. If, on the other hand, as not infrequently happens, the thrombosis leads to occlusion of the deep channels, the superficial dilatation remains permanent and sooner or later a state of ordinary acquired varicosity of the leg follows, which extends, as a rule, no higher than the junction of the two branches already mentioned, and which completes the formation of the femoral saphena, as at this point the blood-current becomes so free that no appreciable change is produced higher up. The clinical importance of these cases is considerable and lies rather in the history of the cases than in the local symptoms.

For practical purposes the only immediate dangers to life arising from varicose veins are: (1) the occurrence of profuse bleeding from the "bursting" of a thinned vein; and (2) the formation of thrombus, which may either rapidly extend to the great venous channels or lead to the detachment of emboli, which if large enough may cause immediate death, or if they pass through the heart may lodge in the lungs, giving rise to pulmonary lesions which are sometimes fatal.

There is no doubt that so far as the limb below the knee is concerned, in the absence of very gross neglect, results serious to life rarely follow immediately from thrombus in varix. In the thigh and at the knee, however, the matter is altogether different, since a recent clot in a varicose vein in those regions is always a serious and sometimes a fatal lesion; in certain types of varix the gravity of thrombus cannot be overestimated.

The local conditions predisposing to thrombosis in varix are: (a) cysts or acute bends in greatly dilated vessels; (b) peculiarity of situation with regard to mobility; and (c) liability to injury. Now traumatic thrombus in varix almost invariably begins either in cysts, cystic dilatations, or in the acute bends of very tortuous and greatly dilated vessels. In situations in which the affected veins,
especially if very large, are continually subject to mobility—e.g., alternate bending and straightening—thrombus is prone to form. The effect of traumatism as a cause of thrombosis is too familiar to require comment.

The tendency of thrombosis in varix to spread and invade the great deep, venous channels increases with the size of the vein, the absence or inadequacy of the vein valves, and especially with the existence of a gross lateral communication between the part in which the clotting occurs and the main deep venous channel nearest in relation to it. The liability to embolism will of necessity be increased by the same condition; upon these conditions, therefore, may be said to depend the gravity of thrombosis in varix. Of the constitutional states predisposing to thrombosis it is unnecessary to speak; they act in the same way, but with more force, in varix as they do under normal local conditions.

SOME DETAILS IN POSTERIOR GASTROENTEROSTOMY.

Barker (The Lancet, Nov. 12, 1898) calls attention to the fact that some operators of large experience who in the past have done many anterior gastroenterostomies are now giving it up in favor of the posterior method. And one, Professor Carle, of Turin, writing at the beginning of this year, claims to have done his last twenty-three posterior gastroenterostomies consecutively without a death, and puts his gross mortality at 3.8 per cent for non-malignant cases. It may be objected to this series that it only contains non-malignant and consequently less severe cases. But, on the other hand, it probably gives a better idea of the intrinsic risks of gastroenterostomy per se than one including malignant cases, many of them probably operated on in the last stages of an exhausting disease.

It is hardly ever necessary to make in the first instance an opening in the muscular wall of more than two inches. The skin wound may be double that length. But with one or two fingers in the abdomen the stomach can in most cases be explored adequately, and during this exploration there is a minimum of exposure of the viscera and very little chance of prolapse of bowel.

Barker then mentions two modifications of the usual operation which he finds save time and a good deal of unnecessary manipulation of the field of operation. Although disclaiming wholesale belief in the use of Murphy's he thinks that in this particular case of posterior gastroenterostomy it has great advantages. Its use certainly makes an operation, which without it is very difficult and tedious, comparatively easy and short. Besides, some of the objections to its use in the anterior operation have less weight in the posterior. Two drawbacks to the use of the button in the anterior operation occur at once to any surgeon who has done many of these operations. One is the probability that the button will fall back into the stomach rather than pass into the bowel. This has been known to occur in several cases. It can be explained both by the weight of the metal body tending to drag it back from its position in the anterior wall of the stomach into the cavity of the viscus, and from the narrowing of the jejunum due to the dragging of the colon preventing the button from passing into the gut. But when the button is placed in the posterior wall of the stomach behind the colon and in the jejunum behind the latter, where it does not kink, the contractions of the stomach and gravity both tend to carry it into the gut, which is at its greatest size and in no way displaced.

Again, two small details in the method of applying the button in the posterior operation which Barker has observed in his last two gastroenterostomies materially shorten the procedure and further minimize the chance of the button falling into the stomach. The first is Professor Carle's method of closing each viscus round the central tube of the button, which differs materially from that recommended by Dr. Murphy. The incision in each viscus was made only just large enough to get the button in. Then, instead of the usual purse-string suture round the edges of the opening to close it on the central tube, Professor Carle simply puts a stitch at each end of the slit by Lembert's method and so reduces it. This saves much time and is equally effectual. It also saves much handling and dragging of the parts.

The next point is a departure from von Hacker's procedure in his operation. He recommends that when the stomach has been reached through a slit made in the transverse mesocolon it should be secured there by stitches before being made to anastomose with the jejunum. The author believes that this stitching may be dispensed with altogether when the button is used. That this will save much time is obvious. In Barker's last case the operation had lasted seventeen minutes before this stage had been completed, the whole procedure lasting thirty-six.
minutes. From what he has seen in the last two cases he has operated on he believes that all that is necessary is to make a small hole in the mesocolon and draw the posterior wall of the stomach through it to a sufficient extent to give room for the insertion of the metal button. When the latter has been placed in position it will prevent the stomach from slipping back through the slit in the mesocolon, and there will therefore be no reason for stitching the latter to the stomach. There might be some fear perhaps that the funnel of the stomach wall thus made might be strangulated by the edges of the hole in the mesocolon, did we not know that under similar conditions where the stomach is drawn out through small apertures, as in the most recent operations for gastrostomy, no strangulation takes place. In his first posterior gastroenterostomy, though the stomach wall was tightly grasped by the hole behind the button, no evil result followed, and the button was passed on the fourteenth day, the patient making a perfect recovery. In his last case of the posterior operation done with the same button he stitched the stomach to the mesocolon. But though the patient made an uneventful recovery and the button was passed on the twelfth day, he could see that he had lost at least ten minutes in putting in stitches in a very inaccessible part which might have been avoided. Everything which gets rid of the necessity of stitching within the abdomen appears to deserve very careful consideration as a means of saving time and the irritation of manipulation.

In conclusion, Barker says he was struck with the very small amount of general disturbance produced by the posterior operations as contrasted with a much larger number of anterior gastroenterostomies which he has done.

Barker then details two operations in which he employed the above method.

A SERIES OF CASES OF CHOLEDÓCHOTOMY, INCLUDING THREE OF DUODENOCHOLEDÓCHOTOMY.

Mayo Robson publishes a contribution on this subject in the British Medical Journal of November 5, 1898, in which he states that in operating on the gall-bladder and bile ducts it is better to begin with an open mind, prepared for any of the various operations on the biliary passages, as it is as a rule quite impossible to say what will be required until the ducts have been explored by the fingers and the condition of the parts ascertained. Although Courvoisier states that gall-stones are found in the common duct in four per cent of all cases, “which possibly may be correct from a post-mortem point of view, or if all cases of cholelithiasis with only slight symptoms are taken into account,” from the surgeon’s point of view he thinks twenty per cent will not be too high an estimate, and this is easily accounted for by the fact that it is only in the cases producing serious symptoms where the opinion of the surgeon is sought. Seeing, then, that one case in every five of gall-stones may probably require some operation on the common duct, it is worth while considering what means are at our disposal.

In a few cases concretions may be manipulated backward into the cystic duct, and thence extracted by scoop or forceps, but it is seldom practicable on account of the contraction of the gall-bladder and cystic duct. The writer has adopted this method successfully on two occasions, but in both cases the cystic duct was also dilated and occupied by concretions.

Occasionally a small stone may be pressed into the duodenum, but this is exceptional and not generally to be recommended, as not infrequently it may be pushed into a dilated diverticulum of Vater, and so be missed, and the whole operation rendered futile.

Cholecystotomy, with subsequent treatment of the obstruction by solvent injections of olive oil or soap solution, is well worth bearing in mind on account of its simplicity and safety, together with the certainty of giving immediate relief with a modicum of risk, and putting the patient in better condition for subsequent treatment should such be necessary. It is of special value in patients too ill to bear a prolonged operation.

Cholelithotritry, or crushing the stones in situ where the concretions are sufficiently soft to yield to the pressure of the finger and thumb, is a method of treatment that Robson has followed on thirty occasions with marked success and without a death; it is especially applicable to cases where the common duct is difficult to reach, as in very stout subjects, or where it is desirable to avoid prolonging the operation. It is only available in the case of soft concretions, and may have to be supplemented by injecting the ducts with a solvent solution.

Needling concretions through the duct walls, recommended by certain operators, is not unattended by danger, as the damage
the walls of the ducts may lead to subsequent trouble. It is of no avail for soft stones, and uncertain in the case of hard concretions.

Cholecystenterostomy, or short-circuiting the obstruction, may be adopted where the patient is too ill to bear a prolonged operation, but it is by no means an ideal operation, as it leaves the obstruction untouched. Moreover, since in gall-stone obstruction the gall-bladder is usually contracted, in the greater number of cases, cholecystenterostomy is not available. The writer has performed the operation thirteen times altogether, but only seven times for gall-stones in the common duct. He lost one patient, who was at the time extremely ill with suppurrative cholangitis and deep jaundice of long duration.

Choledochenterostomy, or uniting the dilated cystic or common duct to the duodenum, in cases of largely dilated ducts with contraction of the gall-bladder, may be called for on rare occasions. The writer has twice done it, and both patients recovered.

Choledochostomy, or attaching the dilated duct to the surface and draining it, is so frequently associated with infection of the ducts in the liver that in nearly all the cases reported a fatal result has followed. The operation is rarely called for. The writer has only done it once, and as there was no infective cholangitis the patient recovered and is now well.

Choledochotomy, or incising the duct and removing the calculi, is the operation par excellence for the treatment of gall-stones impacted in the ducts and which cannot be removed by any simple means.

Duodencholedochotomy, or reaching the duct through the opened duodenum for stones impacted in the duodenal end of the duct, is a useful modification of the operation.

It will thus be seen that the surgeon has a great variety of operations to choose from; and he will act the wisest who, knowing all, is able on the spur of the moment to choose that peculiarly adapted to the case in hand.

The purpose of this paper is to record the author's experience of the operation of choledochotomy, which is the ideal operation for gall-stones impacted in the common duct, and the following remarks, as well as the list of cases, refer to this operation and its modification, duodencholedochotomy.

An oblique incision through the parietes, along the lower border of the right lobe of the liver, gives more room than the vertical, where the common duct has to be operated on, but if the vertical incision be employed, it must be made larger than the one for simple cholecystotomy.

A sand-bag under the loin brings the duct several inches nearer the surface, and is therefore of great utility, and Robson always employs it. Two assistants are advantageous, one to retract the stomach and intestines on the left by means of a firm flat sponge and a wide retractor or his fingers, having his right hand free to sponge away the bile flowing from the incised duct, and another to retract the right side of the wound, the liver, and right costal margin. The operator then, after adhesions have been separated, grasps the common duct between his finger and thumb, and makes it prominent, when a vertical incision may be made over the stone, which can be gently squeezed out or removed by scoop or forceps.

It is of the utmost importance to clear the ducts or the operation will be futile, as shown by Kehr, who left concretions behind in 16.6 per cent of his cases, and by Riedel, Terrier, Fenger, Lauenstein, Küster, and others. Fenger has suggested a flexible metallic probe, which he says will give a click when it touches a stone, or which will produce a grating sensation when it passes one. This the writer knows by experience to be a fallacious guide, as after carefully probing, and even passing a scoop into both hepatic ducts and up and down the common duct without feeling a calculus, the author inserted his finger through the incision and felt a stone, which he was then able to remove, but had he trusted to a probe he would inevitably have left it. The duct is usually dilated sufficiently to permit digital exploration, which under such circumstances Robson always advises, reserving a bent probe, or better still, a slender bent scoop, for use where the duct is not capacious enough for the finger. The hepatic duct and its primary branches can be readily explored, and he has removed calculi from them through an incision in the common duct.

For applying sutures he either uses a rectangular cleft palate needle or a simple round intestinal needle, usually discarding any needle holder. The first sutures of catgut bring together the edges of the muscular and fibrous coats, the final sutures of silk the serous covering of the duct.

The author usually inserts a rubber tube and gauze drain, and leaves it in for twenty-four hours, or longer if needful, and generally at the same time drains the gall-bladder as in an ordinary cholecystotomy. Where the concretions are impacted in the duodenal
end of the duct, it is very much easier and more effectual to get at them through the incised duodenum, which he has done on three occasions, all the patients being now well.

The operation of removing gall-stones from the duodenal end of the common duct through an incision in the duct was first performed by McBurney, then by Pozzi and Kocher.

The operation is really less difficult than it would appear, and is much facilitated by placing a sand-bag under the lower dorsal spine. In each case he has grasped the termination of the common duct, including the duodenum, between the left finger and thumb, and has then cut through the anterior wall of the gut, exposing the interior of the posterior wall of the intestine, with the termination of the common duct running in it. In two cases the writer laid open the duct from the papilla, and in another cut directly on the stone through the posterior wall of the duodenum. Bile flows freely as soon as the obstruction is removed, and it must be mopped away as it flows by gauze pads, as it always contains pyogenic organisms, and is therefore infective. In none of his three cases has there been any trouble with bleeding, and no sutures have been placed in the incision in the posterior wall of the duodenum. The incision through which the duodenum has been opened—vertical in two cases and horizontal in one—is then sutured by a continuous catgut suture for the mucous membrane, and continuous silk suture for the peritoneum. No drainage is required.

As in all these cases of obstruction in the common duct jaundice has been present over a longer or shorter period varying from months to years, and as in long-continued jaundice there is a tendency to bleeding, Robson is in the habit of giving all his cases, for a few days before operation, chloride of calcium in half-drachm doses thrice daily, and of administering it in a nutrient enema in one-drachm doses thrice daily for twenty-four or forty-eight hours after operation. Since adopting this method of treatment he has had little or no trouble from hemorrhage, either at the time of operation or subsequently, and he confidently recommends it as a useful measure.

The prognosis of choledochotomy will improve with experience, though it will probably be more serious than simple cholecystotomy, not only on account of the various complications of jaundice and infective cholangitis, but because of the greater technical difficulties of the operation itself.

In 1886 Kehr collected from all sources eighty-four cases, with a mortality of 37.8 per cent, though his own mortality was only 6.6 per cent. The total number of operations is so few, and performed by so many different operators, that the conclusions to be derived from statistics are at present misleading. Moreover, another factor has to be taken into consideration, in that in some of the simpler cases of gall-stones in the common duct choledilithotomy may be performed, whereas if these cases were all submitted to choledochotomy it would give the operation a much more favorable appearance. For instance, he has operated directly for gall-stones in the common duct in forty-nine cases, with three deaths, equal to a mortality of 6.1 per cent. These deaths occurred, one after cholecystenterostomy and two after choledochotomy, and in all three the jaundice had been long continued and deep and associated with infective or suppurative cholangitis. Among the choledilithotrites there was no death, but among the seventeen choledochotomies there were two deaths, equal to a mortality of 11.7 per cent. As experience increases, Robson believes and hopes that the mortality will be reduced to five per cent, though even if the mortality remain higher it must be borne in mind that nearly every recovery is a life saved, for in the greater number of these cases of gall-stones in the common duct death after prolonged suffering is the usual termination.

CONTUSED WOUNDS OF THE ABDOMEN AND THEIR SURGICAL TREATMENT.

ROGERS (Medical Record, Oct. 8, 1898) states that the chief points to be considered in making a diagnosis of grave intra-abdominal lesions are the history of injury and its location, character of vulnerating force, rigidity or boardy condition of abdominal walls, obstipation, vomiting, pain, anxiety, and restlessness, the degree of shock and prostration. Pulse and temperature may be taken as reasonably safe guides in making a prognosis. Depending upon degree of shock, the pulse is at first rapid, irregular, and weak; temperature subnormal or normal. In favorable cases the pulse becomes stronger and regular, temperature normal or above normal. In unfavorable cases the pulse continues weak, intermittent, becoming hard and wiry; the temperature fails
to reach normal, or there rapidly supervenes a condition of hyperpyrexia.

It is better surgery to open the abdomen in doubtful cases and find no lesion than wait in a single instance until signs of septic peritonitis are present. An aseptic exploration will do no harm, while delay means death in ninety-six per cent of all cases of rupture of the intestine. A free incision should be made in the median line, and injured organs located as quickly as possible. This is oftentimes difficult. In locating the seat of injury the exact point at which violence was applied should be remembered. After injury of this character there is paralysis of the bowels, and in most cases rupture will be found immediately beneath the point where vulnerating force came in contact with the abdominal wall.

Of further importance is the action of the omentum, especially where considerable time has elapsed after receipt of injury; and in many cases of rupture or injury to viscera the cemen tum throws itself into the breach, and endeavors by adhering to the wounded organ to protect the general cavity from infection. A large portion of omentum will be found adherent at the point of rupture, and adds much to the ease of locating injury.

The prognosis is much more unfavorable if it is necessary to expose intestinal coils, which procedure adds much to the shock of operation, so much indeed that death almost invariably occurs when evisceration is necessary. It is doubtful if such procedure is ever necessary or justifiable.

THE BLOOD IN SEPTIC DISEASES OF THE ABDOMEN AND PELVIS.

Herbert Maxon King (Medical Record, Oct. 8, 1898) is unable to find any evidence which points to existence of characteristic blood conditions in sepsis arising from pelvic or abdominal causes, as distinct from sepsis from foci in other parts of body, and thinks none can be admitted. A felon may produce leucocytosis alike in kind and degree with that of septic peritonitis, since the cause of both is the same, while the diseased area involved makes little if any difference.

Blood examinations are of inestimable value as diagnostic aids in distinguishing between sepsis arising from pelvic and abdominal sources and certain diseases which in other clinical appearances simulate it closely.

Leucocytosis is always present in sepsis, except in severe infections which result fatally within a few hours; it is absent in intestinal obstruction (when not cancerous), cystitis, endometritis, tuberculosis (when uncomplicated), typhoid fever, and malaria.

Malignant disease is hardly to be confounded with sepsis; but if the question arises certain morbid changes in the red cells, principally of necrobiotic character, are almost always found in the former, while such changes are rarely, if ever, noted in sepsis, however protracted the case. The question may arise as between catarrhal and suppurative appendicitis, in which the blood-count, in the opinion of some observers, is of diagnostic value.

In a true inflammatory condition about the appendix, leucocytosis may be very slight or absent altogether. The study of blood also aids in the prognosis of septic disease, and as indication for operative interference surgeons are more and more availing themselves of its aid; and with establishment of clearer comprehension of the causes of leucocytosis and the origin and destiny of various elements, both normal and pathologic, in blood, a new light will be thrown upon the diseases under discussion, as upon many others which lie farther within the realm of speculation.

RESECTION OF THE INTESTINE FOR MALIGNANT GROWTH SUBSEQUENT TO OPERATION FOR INTESTINAL OBSTRUCTION.

Mr. Battle (Medical Press, Oct. 5, 1898) operated on a woman aged twenty-eight, on whom he had previously operated for chronic obstruction of bowels. There had been intestinal obstruction of three months' duration, the cause of which was diagnosed as malignant stricture of the large intestine, probably situated in the descending colon or sigmoid flexure. Median incision was made to discover the exact seat of obstruction, and when this was located at the splenic flexure an artificial anus was made just above the opening in the abdominal wall, being well to the outer side of the linea semilunaris and a short distance below the ribs. A loop of intestine was brought out and retained in position by means of a pair of Spencer Wells' forceps, passed through the mesentery, after which a Pauls' tube was fastened in the upper part of coil. Convalescence was slightly retarded by localized cellulitis, but a month after operation all traces of obstruction had disappeared, and the patient had improved greatly in health.
The patient having been placed under ether, and the opening into the bowel having been closed with a plug of cyanide gauze, an incision was made along the linea semilunaris for four inches below the artificial anus. A piece of gauze was next passed into the abdominal cavity to the outer side of the colon. The growth, which was well localized, could be brought to the surface; there did not appear to be any glandular enlargement present. The bowel below the growth was clamped by means of a piece of rubber tubing passed through the mesentery and held with artery forceps; the bowel was cut across and the mesentery behind the growth cut near the gut, the vessels being caught as they showed themselves. The bowel was secured in a similar way above. The artificial anus was separated from its attachments to the abdominal wall, the main incision being extended into it from below; the piece of gauze was removed from the upper end, the bowel was washed out, and a section was made above. The growth and bowel from two inches below the disease to above the artificial anus were then removed. During this procedure the abdominal cavity had been shut off by means of flat sponges. Lateral anastomosis was then effected in the following manner: The ends of the gut were turned in and closed by continuous Lembert sutures; the upper portion was placed to the outer side of the lower one so that when sutured it would lie above and external to the latter. A row of interrupted Lembert sutures was placed about half an inch behind the line selected for opening; the opening was then made about two and a half inches long in both portions of bowel, and a continuous stitch, including all the coats, was passed to unite the opposed edges. Interrupted Lembert sutures were then inserted in an outer row, surface of peritoneum being thus closely apposed for a distance of half an inch around the main opening. The parts were carefully cleansed, gauze and sponges being removed, and a portion of omentum was placed over the band which had thus been united. The abdominal wound was then closed in two layers, the peritoneal and subperitoneal tissue with fascia being first shut off. The ordinary dressings were applied.

Mr. Battle said the case illustrated the importance of doing resection of the large intestine in two stages, in cases of disease which had produced obstruction. It was never advisable to perform resection on a patient who was suffering from obstruction, when neither the general nor the local condition was favorable. In the case under consideration, at the first operation, the patient was exhausted with vomiting and want of food, whilst the distention of the abdomen prevented the mesentery under the growth from being brought out. He had selected lateral anastomosis in preference to end-to-end anastomosis, for he was of opinion that lateral anastomosis was much the safer method of operating. In the same way he considered that the fewer mechanical contrivances in the shape of clamps that were used the better for the bowel; also it was preferable to avoid the use of bobbins and buttons when possible.

The patient has progressed favorably with the exception of a tendency to bronchitis, the effect of the prolonged etherization. The growth was probably cylindrical carcinoma, which had almost completely occluded the bowel.

FOREIGN BODIES IN THE EAR.

HUMMEL (Münchener Med. Woch.; Medical Record, Oct. 8, 1898) makes the following deductions: (1) The relation of the normal ear canal to inanimate foreign bodies is entirely without reaction; that is, a foreign body in the ear does not, per se, endanger the integrity of the ear. (2) Hasty endeavor at removal is not only unnecessary, but can become very injurious. (3) In all cases not previously interfered with (with few exceptions) foreign substances can be removed from the ear by syringing. (4) General practitioners should never employ anything but the syringe in endeavoring to remove foreign bodies from the external auditory canal. (5) Instrumental removal of foreign bodies from the ear should be effected only by one fully able to examine the ear with the otoscope and acquainted with every operative manipulation in this region.

NOTES ON THE TECHNIQUE OF SKIN GRAFTING BY THIERSCH'S METHOD.

ARTHUR E. BAKER, F.R.C.S. (Practitioner, October, 1898), says that the instruments required are few: a pair of scissors and forceps and a broad flat razor are all that are necessary. The latter is best sterilized by being immersed in spirit, which does not spoil a fine cutting edge as does boiling. Later and during operation it should be dipped in a
mixture of glycerin 25 per cent, spirit 25 per cent, boiled distilled water 50 per cent. This will lubricate the blade and enable thin grafts of epidermis to slide or float out on the steel instead of gathering into shapeless wisps.

Skin from which grafts are to be taken, usually the front of the thigh, should be very carefully cleansed on several occasions. A day or two before operation this process should be begun by a warm bath of the whole body. After this the thigh is washed briskly with methylated spirit and wrapped for a couple of hours in a towel wet with 1-in-20 carbolic lotion and covered with oiled silk. Next day the same process is repeated, during which there will probably be some exfoliation of epidermis, due to the irritation of the carbolic acid. This is very salutary, as it carries off superficial layers which contain the largest number of microbes. The skin should then have a rest until a couple of hours before operation, when a carbolized towel is again applied and left on until the patient is on the operating table.

Supposing rodent ulcer of the face is to be removed and grafted; the skin of the affected side is treated as above, and finally washed with spirit. The growth is then removed freely, bleeding vessels being closed by pressure forceps. The cavity left is filled with a sterile sponge or sterile gauze until all oozing has ceased. In the meantime the thigh is washed thoroughly with spirit. When the wound has ceased oozing, the razor, wet as above in glycerine mixture, is used to shave off from the thigh the thinnest possible graft. The latter should consist only of epidermis down to the papillary layer. If it contains any of the latter it will curl up and become unmanageable. The larger the graft is, compatible with its thinness, the better; as a rule it will amount to about an inch square. As it now lies on the blade of the razor it may be spread out with the tip of the finger or a forceps. A sterile sponge is now taken and pressed against the graft, and the razor is drawn away, leaving the graft on the sponge. Here it may require to be spread out a little further. The wound is now uncovered, and if oozing has ceased the graft, sticking to the sponge, is pressed down upon it, and it will adhere, the sponge coming away after absorbing the moisture pressed out from under graft. Then another graft is placed over any raw surface left uncovered, and slightly overlapping the first, and so on until the whole wound and its borders are covered. A large pad of sterile gauze is laid gently over the whole wound after each graft, and gently pressed upon by an assistant, while the graft is being prepared; it is then lifted gently by one end until the latter is in place, when it is again laid down. Each time it removes all moisture.

If a granulating surface is to be covered in, the surface of the healing ulcer is first scraped with a blunt-edged spoon until the superficial layers of cells have been removed. The bleeding is next arrested carefully by pressure, as above. The grafts are then cut and applied as described. It is a mistake to scrape too deeply through an ulcer, as the tissue then left on its base is unsuited for grafting, consisting mostly of fibrous tissue.

In both instances the dressing should be a pad of sterile gauze or salicylic wool pressed evenly into every corner of the wound upon the grafts. This serves the double purpose of squeezing out any moisture from under grafts and bringing all the surface of the latter into close contact with tissues underneath. This pad is covered with more of the same material, so as to give good elastic pressure over whole surface. It should be left untouched for six or seven days, and should then be soaked in lotio boracis until quite soft before being loosened.

Of course, such a dry dressing pressed directly upon grafts, and more or less infiltrated with blood, will form a hard cake at the end of a week or so, firmly adherent to the grafts. There might be some fear then that they would pull off the latter when removed. But, on the other hand, if deeper layers of the graft have not firmly united to the wound by the end of a week they will not unite at all, and had better be removed. What is usually seen when the dressing is first removed is that the superficial or dead layers of epidermis have stuck to the dressing and have come away with it, but leaving deeper and essential cells behind.

In many cases, however, when the first dressing is taken off at the end of a week, the thin, bluish-white area of cicatrization is seen to be well advanced. In those cases where the base of the defect to be covered lies at a much lower level than the general surface of the skin, as in a wound left by the removal of a rodent ulcer, grafts must be made to cover the vertical edges closely before resting on the horizontal base. When first healed the appearance is remarkable, but in the course of time the base of the defect rises, and the edges thin down until the new cicatrix is almost on a level with the sur-
rounding skin. The wound made on the thigh during the removal of the grafts requires only a boracic lint dressing to be left on for a week. So complete is the restitutio ad integrum that in a month or two it is almost impossible to say from what surface the grafts had been removed.

ONE HUNDRED CAESARIAN SECTIONS.

Leopold and Haake (Quarterly Medical Journal, October, 1898) have published recently in the Archiv für Gynakologie, Band lvi, Heft 1, an article upon 100 Cesarian sections (see also Ann. de Gynec. et d'Obst., June, 1898). As Professor Leopold has performed more Cesarian sections than any other man, alive or dead, a special value attaches to his experience and conclusions. The series extends over a period of rather more than fourteen years, and all except the first were performed at the Königliche Frauenklinik at Dresden. Seventy-one were "conservative," 29 were mutilative—i.e., Porro's operation. The 99 operations at Dresden corresponded with 22,358 labors, or one in 2258. The first 50 cover fifteen years, the second nine years. This increased frequency is due to the greater confidence and readiness in resorting to operation which perfected antisepsis has brought about.

The indications for operation are either "absolute" or "relative," relative indication referring of course to cases where operation is performed as an alternative to possible empyematyotomy. But it must be emphatically laid down that relative indications must only lead to conservative operation where the condition of the most rigorous antisepsis can be realized. In contracted pelvis the relative indication recognized at the Dresden clinic is a true conjugate of less than 6 centimeters (2.36 inches), but such figures are only an approximate guide. Clinically the indication may be more absolute with a true conjugate of 6.5 centimeters and a large child, than with a conjugate of 5.5 and a small child. The limit for version followed by immediate extraction with the employment of Walcher's position is a true conjugate of 7 centimeters (2.73 inches) in flat, rickety pelvis, and 7½ centimeters (2.96 inches) in flat, generally contracted, pelvis.

In considering the indications for Porro as opposed to conservative Cesarian section, the authors say that Porro should be done when the following conditions are not rigorously fulfilled: (1) The parturient woman must have energetic uterine contractions; (2) the constitution must not have been weakened by serious illness; (3) it must be certain that the patient is not already infected. It is also desirable that there should be no marked elevation of temperature or acceleration of pulse. It is very desirable that the membranes should not be ruptured, or ruptured but very recently before operation. It is essential that there should have been very little examination, and none by hands of doubtful asepsis. Above all else, there must be no suspicion of gonorrhea, acute or latent. The authors advise for this reason a bacteriological examination of the secretions of the vagina and cervix. If gonococcus be found, Porro may be safer than perforation. Nephritis is another contraindication.

Fifty-five of the 100 cases were multipare. These had had 108 previous confinements, namely, 9 miscarriages, 7 premature children (2 living, 5 dead), 15 spontaneous deliveries at term (10 living children and 5 dead); instrumental and operative deliveries, 77. But 14 of these confinements were Cesarian sections; the remaining 94 had yielded 23 living children, a fetal mortality of 83.6 per cent. In 13 of the 100 operations, section was performed more than once on the same patient, viz., on one four times, on another three times, on eleven patients twice. As regards mode of operating in conservative Cesarian section, the elastic ligature was used in most of the cases. If but moderately tightened and not left too long in situ, there is no inconvenience from its use. It is especially adapted for operating when short of skilled assistance. Silk is used for sutures. Twelve to fifteen deep sutures are inserted one centimeter from the peritoneal edge; they traverse the muscle in a curve and emerge at the inner edge of the wound. Between these are thirteen to seventeen sutures which pass through peritoneum and superficial muscle only. Ergotin is injected at the commencement of anesthesia, and again just before operation.

RESULTS.

The authors say that three of the conservative operations and two of the Porro's owed their death to causes not strictly incidental to the operation, and that this would reduce the total mortality to 5.2 per cent. We read-
ily recognize the fact that in such a long series of cases some would be operated on under very disadvantageous conditions. As to the fetal mortality, in all the seventy-one conservative operations the child was born alive, but five died before the mother left the hospital. In the Porro series, one was born before operation, three died before operation, two died during the labor, and two after birth, from intestinal catarrh.

**Sequela.**—In 51 cases, no fever; in 13, slight fever; in 13, complication of septic nature.

**THE SURGICAL TREATMENT OF GOITRE.**

**Reverdin** (La France Méd. et Paris Méd., Oct. 14, 1898), after describing briefly the various operations practiced for the relief of the symptoms dependent on goitre, analyzes over six thousand cases, and deduces from this that the mortality incident to operation is less than three per cent. Total extirpation shows a mortality of 18.9 per cent, while intraglandular enucleation shows but .78 per cent. The latter operation should, then, be given the preference.

As to the accidents and complications attendant on the operation, lesions of the veins are dangerous because of the possibility of air embolism. The author states that he knows of nine fatalities due to this cause. Each vein should be divided between forceps or ligatures.

The primary hemorrhage in the case of glandular tumors may be so free that enucleation may have to be abandoned in favor of excision. By proceeding slowly and deliberately and keeping to the capsule of the new growth the bleeding rarely gets beyond control.

The recurrent laryngeal nerve may be wounded in excision. Kocher states that such an accident occurred in seven per cent of his cases; enucleation greatly lessens the danger of this complication, which is best avoided by careful isolation of the inferior thyroid artery before it is tied. The superior laryngeal, the hypoglossal, and the sympathetic nerves, the trachea, larynx, esophagus, and pleura have been wounded exceptionally.

For the purpose of lessening the danger of infection the wound should be closed. Even when it runs a sterile course there is commonly a distinct fever, named by Poncet thyroid fever, supposed to be due to absorption of the thyroid secretions.

Pneumonia is a common sequel of operation; its cause is obscure.

When the trachea has been greatly affected by pressure atrophy, on the removal of the surrounding tissues it may collapse on inspiration. This may be remedied by intubation through the larynx, or by holding the trachea open by stitches.

Both tetany and myxedema develop exceptionally after operations. Psychoses such as melancholia, dementia, mania, epilepsy, hysteria, are observed only after total extirpation.

As to the results of operation, a transverse incision neatly sewed leaves a scarcely perceptible scar; the functional troubles are usually cured at once, and recurrences, at least those requiring a second operation, are rare.

When the disease is distinctly limited to one lobe the author prefers unilateral extirpation.

**INTERSCAPULO-TORACIC AMPUTATION FOR THE REMOVAL OF MALIG-NANT TUMORS.**

**Berger** (La France Méd. et Paris Méd., Oct. 14, 1898) reports the case of a man aged twenty-eight who exhibited a tumor, malignant in appearance, three months old, the size of a turkey's egg, which starting from the neck of the humerus had invaded the deltoid and the scapular muscles. Berger cut through the clavicle in its mid portion, ligated the axillary artery and vein, then with very little hemorrhage amputated the upper extremity, including the scapula and its attached muscles, the deltoid, and a mass of enlarged glands in the axilla.

The infiltration was myxomatous, having originated from the medullary cavity of the humerus.

Eighteen months after operation there was no recurrence.

Berger reports the after-history of a second case, on whom he operated fifteen years ago because of an enormous enchondroma. This man is at present an active country postman.

As a result of statistical study Berger states that forty-six amputations of the arm, including the scapula, practiced for the removal of tumor of the humerus, were followed by operative death in but two instances. An infant two years old died, probably of shock. The other fatality occurred at the hands of Bergmann; the malignant infiltration required for its complete ablation, in addition to the removal of the arm and shoulder, a partial resection of the sternum and of the
first rib. Moreover, Bergmann ligated the superior vena cava and tamponed the mediastinum.

Thirty-one of the cases tabulated remained under observation; in fourteen of these recurrence or metastasis was noted, with one exception, in from four to six months. In seventeen there has been no recurrence or metastasis. Ten of these cases have been under observation for more than a year. Since the osteosarcomata are always precocious in their recurrence, Berger holds that these ten cases can be regarded as permanently cured.

This establishes the interscapulo-thoracic amputation as the one of choice in the treatment of malignant tumors of the upper segment of the humerus, since the mortality incident to it is not greater than that which follows scapulo-humeral disarticulation, and since it gives thirty-three per cent of radical cures as contrasted to the almost certain failure of the latter operation.

In the course of a case of acute intestinal obstruction it is possible to recognize three stages. In the first stage—or that of the onset of the trouble—the symptoms are those of intense abdominal pain, collapse, and vomiting. We will assume that the lesion is represented by the snaring of a loop of ileum by a peritoneal band. The symptoms in question, however, are in no way due to the fact that the bowel has become abruptly blocked. They depend upon the circumstances that a sudden and intense impression has been made upon exquisitely sensitive abdominal nerves. The symptoms must be classed as purely nervous. The vomiting, for example, is reflex, and has no connection whatever with the accidental fact that the bowel has become occluded.

The symptoms which mark the onset of a case of acute intestinal obstruction have little or no diagnostic character. They are symptoms which attend all sudden and intense painful impressions upon important visceral nerves, and have been collectively described under the title of "peritonism." They are symptoms common to a series of intra-abdominal accidents. In the absence of any determining feature in the patient's history these clinical phenomena may equally well mark the passage of a gall-stone, torsion of an ovarian tumor, the perforation of an ulcer of the stomach, or the rupture of a pericæal abscess. They are nervous symptoms produced by a common nerve lesion, and their interpretation can proceed no further than this—there has been an abrupt and intense impression made upon some part of the abdominal nerve plexuses. We have all seen cases in which perforation of the stomach or appendix has been mistaken for intestinal obstruction, and vice versa.

In what may be termed the second stage in a case of acute obstruction the symptoms attain more individuality, and depend without doubt mainly upon the mechanical obstacle in the bowel. The pain is to a large extent due to disordered and futile peristaltic movements, the absolute constipation depends upon the blocking of the intestine, and the persistent vomiting is in the main due to the same cause. The character of the vomit, however, shows that another factor is being introduced into the circumstances of the case in the form of rapid decomposition of the intestinal contents. This depends, of course, upon the unnatural retention of those contents in the bowels, and probably in a still larger degree upon vascular and other changes.
in the intestinal wall. The vomited matter becomes offensive, and acquires an odor which for want of a standard of offensiveness may be called stercoraceous. Feculent or fecal vomiting—by which I assume is meant the ejection of feces—I have not met with in acute obstruction. Finally, there is an increasing distention of the abdomen. This is largely due to mere accumulation, to mere inability of the contents to escape. The meteorism in intestinal obstruction is, however, in great part due to vascular changes in the bowel wall. This fact has been fully demonstrated by experiments upon animals and by pathological experiments in man. It is well illustrated by a distention of the twisted loop in volvulus of the sigmoid flexure. The most severe case indeed of meteorism of the small intestine which has come under Treves’ notice was associated with no mechanical obstruction in the gut, but was due to thrombosis of the superior mesenteric vein.

Last of all, in the third or final stage of acute obstruction, the symptoms have little to do with the actual obstruction as such. They are the symptoms of poisoning, and the patient who dies unrelieved dies poisoned. The septic matter which leads to his death is derived from his own intestine. It is the rapid onset of septicemia which makes the operative treatment of acute intestinal obstruction so futile in the majority of cases. In many an instance an accurate diagnosis has been made, an early incision has been carried out, and the cause of the obstruction has been readily discovered and removed. The abdomen is closed and the patient dies. Treves quotes one very painful example of this sequence of events. The patient was a gentleman of middle age; the operation was performed forty-eight hours after the onset of the attack. A strangulating band presented itself the moment the abdomen was opened. It was divided without difficulty and the parietal wound was closed. A more favorable case could hardly be conceived, yet the patient died with septic manifestations, and necropsy revealed no breach in the bowel and no gross peritonitis.

Those who wish to advance the therapeutics of intestinal obstruction must first of all grapple with this terrible element of intestinal septicemia. Surgery wants a Lister who will teach us how to overcome the process of decomposition in the bowel. The lesion to the bowel need be by no means grave; the operation of dividing an easily discovered band cannot be considered to be severe, and yet the patient dies. In a large proportion of these cases there is infection of the peritoneum to a degree which may lead to death, and yet produce few of the naked-eye manifestations of peritonitis; but the infection starts from the bowel, and in the bowel the process of antisepsis must start. The intestine has some power of acquiring immunity against this septicemia, as is made evident in cases of chronic obstruction of the bowel, when one meets with a slighter grade of this self-poisoning, from which the patient makes an easy recovery. Such milder forms are often seen in instances of fecal accumulation. As soon as the fecal mass has been removed there is often some fever of a mild degree and collapse and possible nausea or even vomiting. As a rule such manifestations vanish in a day or so. The stomach seems not to lend itself to this form of blood poisoning, and extensive accumulations may take place in that organ and lead to no septic effects. The colon, too, would appear to possess a natural immunity up to a certain point, but in the lesser bowel the process is uncontrolled, desperate, rapid, and almost hopeless.

From a practical point of view the treatment of acute intestinal obstruction appears to demand two things of the surgeon: (1) An early operation, and (2) the evacuation of the bowel after the strangulation has been relieved. The first of these two measures will be allowed by all to be commendable. The opening of the abdomen in these particular cases is not a trifling measure, but it is infinitely trifling when compared to the mere standing by with folded hands to await the remote possibility of spontaneous cure. The so-called medical treatment of these cases is a relic of the Dark Ages, and must rank with the “faith-cure” and the medical treatment of a dislocated hip.

With regard to the second proposition, it appears in a certain sense that the real danger to life lies rather with the poisonous material in the intestine than with the actual obstructing cause beyond its walls. The patient is dying not because his bowel is occluded, but because the distended gut above the obstruction is producing a poison which is sapping his strength. It has, unfortunately, been too many times demonstrated that the successful relief of the obstruction will often fail to save life, and, indeed, it is of more moment to relieve the patient of the trouble within his bowel than of that which is with-
Reports on Therapeutic Progress.

out it. In all cases of acute intestinal obstruction which have been dealt with in recent years Treves has not considered the operation complete until he had, as a matter of routine, emptied the bowel. This is conveniently done by bringing the most distended coil to the parietal incision, and evacuating it by means of a small glass tube, which is inserted into the gut, and secured to the bowel wall by a single encircling thread. He has had no difficulty in closing the small artificial anus by a subsequent operation, carried out some weeks after the original proceeding. This measure has had the effect of reducing the mortality of this formidable procedure to one-half of its original rate.

To appreciate and deal with septic processes within the bowel must be one of the very first rudiments of intestinal surgery. The teachings of Lister have led to a revolution in the surgeon's art which is still a matter of amazement. Antiseptic surgery, however, as we employ the term, concerns itself mainly with the prevention of forms of infection in which the septic germ is introduced in the body from without. Antiseptic surgery has practically left untouched those forms of infection in which the septic element is in a certain sense introduced into the system from within.

With regard to that infection the remarkable fact is this, that the bacillus which appears to be most concerned in the production of this septicemia is not a bacillus introduced accidentally into the bowel from without, but a bacillus which exists normally in the bowel in a condition of health. It is probable that the microorganisms described under this name do not belong to one particular definite species, and that the term bacterium coli commune may be taken as a collective name for a group of bacteria which will probably be in time resolved into several different species. Anyhow, this widely diffused bacillus exists normally in the intestine of healthy man, and appears in the bowel a few hours after birth. It is found in all parts of the intestinal canal and at all periods of life. It is scarcely reasonable to assume that this invariable occupant of the healthy intestine is a mere noxious or useless parasite. It is more than probable that it is concerned in some direct or indirect way with the process of digestion. It would be indeed interesting to know how the phenomena of digestion would proceed in a sterile bowel.

The bacterium coli may remain in a perfectly harmless saprophyte; on the other hand, it may rapidly alter its character, and become possessed of intense pathogenic activity. It has been shown that in the majority of cases of peritonitis the local inflammation is due to the bacterium coli commune which has escaped from the lumen of a diseased veriform appendix. That extensive variety of peritonitis which takes its origin from the intestine, as illustrated by the peritoneal infection attending strangulation of the bowel, would appear to be, in nearly every instance, due to microorganisms now under discussion.

The virulence of the bacillus coli is subject to quite extraordinary variability. An exaltation of its virulence may be due to an association with other organisms, pathogenic or non-pathogenic; but in most instances its morbid activity is excited by some change in the condition of the bowel itself. Diarrhea, enteritis, cholera, and typhoid fever are all capable of rendering this organism virulent, and the same may be said of the conditions attending fecal accumulation.

Examinations upon animals make it probable that in man a moderate infection of the peritoneum with the colon bacillus from a healthy bowel would be harmless, while an infection by equal dose from a bowel rendered in any way unhealthy would induce peritonitis. Surgical experience would certainly support the suggestion. Klecchi has shown that the bacterium coli from the ileum is the most virulent, that from the jejunum ranks next, while that from the colon is the least potent for harm. There is no doubt that so long as the bowel wall remains intact, especially as regards the epithelium, little or no opportunity is afforded the bacteria to escape from the gut. Artificial compression of a loop of bowel by an india-rubber ring (with or without ligature of the mesenteric vessels) will cause acute general peritonitis in dogs, as Klecchi has demonstrated. The animals die in twenty-four to forty-eight hours. The epithelium rapidly desquamates, the vessels dilate, and there is an abundant infiltration of the whole wall of the ligatured knuckle. The virulence of the colon bacillus within the loop is infinitely greater than that of the same microorganisms from an undisturbed part of the same intestine.

These facts suggest by the way that the handling of the bowel during an operation should be of the gentlest, and that the evacuation of an obstructed loop is very desirable. On the other hand, there is no
doubt that the normal peritoneum has considerable power of resisting an invasion of this particular bacterium. This protective power, however, would appear to be very soon lost if the delicate surface of the serous membrane be damaged. There is no doubt that the washing and scrubbing and rubbing to which the peritoneum was exposed while surgeons were under the influence of that fatal expression “the toilet of the peritoneum” led to many deaths.

The peritoneum has remarkable powers of protecting itself if only the surgeon will permit it to exercise them. Save in a few exceptional instances, the serous membrane is better able to deal with a moderate effusion than are the overready sponge and the futile and often fatal drainage tube.

Treves has noticed, moreover, that the peritoneum which has been subjected to repeated infections becomes in time almost immune. The operations which can be carried out with success in patients who have repeated attacks of peritoneal inflammation are often almost beyond credence.

The average colotomy gives the patient but a minimum amount of trouble. In a large proportion of cases it is possible to secure a good action of the bowels every forty-eight hours, the artificial opening causing the patient but little or no inconvenience in the interval. If there be a degree of colitis present at the time of the operation, it is true that the new opening may be the seat of a not inconsiderable distress. But in the average case the administration of a dose of mistura alba very early in the morning on alternate days will secure an ample evacuation of the bowel followed by a period of immunity from disturbance. This much-to-be-desired result is rendered possible by very careful feeding, and above all by the utmost attention to the wound. There is no doubt that the troubles attending colotomy, as performed some years ago, were in large measure due to neglect of the wound. A pad of septic tow and a dab of vaselin were placed over the bowel, and the requirements of surgery were considered to have been thereby fully met. The gross neglect of the part was excused on the ground that the operation area was already septic. As a matter of fact, few complicated wounds respond more readily to careful treatment and assiduous attention than does the colotomy incision, and the benefit to the patient from such care can hardly be overestimated.

It is satisfactory, however, to note that the necessity for colotomy is rendered less frequent by the numerous opportunities for performing resection of the bowel, especially for cancer, and by the excellent results which have followed upon the operation of lateral anastomosis or short-circuiting. The incision of a portion of the colon for malignant disease must rank as a most satisfactory procedure. The best results are obtained when the growth is situated in the sigmoid flexure, or in such other part of the large intestine as may be provided with a free mesocolon. The least satisfactory cases are those in which the growth has involved a part of the bowel which is unassociated with a mesocolon and has a portion of its surface denuded of peritoneum. It is essential for success that the growth should be dealt with early, and that the excision of the gut and of the associated mesocolon should be as liberal as possible. Indeed, it appears that among all operations for the treatment of cancer by excision the removal of a portion of the sigmoid flexure for early epithelioma must rank as one of the most successful.

In those instances in which the malignant growth, by reason of its position or extent, cannot be removed, there are, happily, a fair proportion of cases in which a lateral anastomosis can be carried out, and the patient thus spared the inconvenience of a colotomy. Experience has shown that a considerable portion of the intestine can be thrown out of the circuit without apparent inconvenience to the patient.

Many of the intestinal sutures, are hopelessly bad, because the thread passes through all the coats of the bowel and acts as a vehicle for conveying septic germs from the lumen of the gut to the peritoneum. Others are hopelessly complex, and of interest only to those who find delight in ingenious puzzles. Not a few are the subject of periodical invention, whereby the forgotten Jones-Robinson suture of 1806 becomes the quite original Smith-Johnson suture of 1898. The best stitch is still the ancient one, which includes a fine continuous suture of the mucous membrane, and points of Lembert suture, which involve the outer coats of the viscus. Certainly in the stomach no form of stitching is more convenient than this. Moreover, among the horde of intestinal needles, the best is the milliner’s needle which comes from the draper’s shop.

Of the methods of uniting a divided bowel, either after excision or in the performance of a lateral anastomosis, the best theoretically is,
without doubt, the method of simple suturing. In practice, however, this can seldom be advantageously employed. The simple suture involves a great expenditure of time; the differences in the segment of gut above the stricture and that below it render straightforward suturing almost impracticable, and the bowel at the suture line is very apt to kink. To cope with these difficulties there has arisen that remarkable host of plates, disks, tubes, cylinders, buttons, and bobbins which has so disturbed the peace of the surgeon who hungers after the "last new thing." Not a few of these appliances alternate between oblivion and rediscovery, to the great hindrance of progress. For example, in 1882 Treves described a method of suturing the bowel over a collapsible india-rubber bag which was sausage-shaped, and was introduced into the ends of the gut to be united. It could be blown out into the form of a firm cushion, and, before the last stitches were introduced, could be emptied and withdrawn. A little experience showed him that his bag was useless, and it was promptly discarded. Now after a period of sixteen years an American surgeon, Dr. W. S. Halsted, redisCOVERS his useless bag, and reproduces it with singular exactness. Halsted believes his old-new procedure to be "better than any method hitherto devised"—and so we step back sixteen years. Dr. Halsted also, by the way, expresses his conviction "that there should be a law compelling all surgeons to practice on animals the operation for circular suture of the intestine and for intestinal anastomosis." It is hoped this view will not commend itself to the legislators of this country. Many years ago Treves carried out on the Continent sundry operations upon the intestine of dogs, but such are the differences between the human and the canine bowel that when he came to operate upon a man he found he was so much hampered by his new experience that he had everything to unlearn, and that his experiments had done little but unfit him to deal with the human intestine.

Of the various appliances in vogue for the uniting of divided bowel the best is Murphy's button. It is very far from being a perfect instrument, but it compares at least very favorably with the other forms of apparatus which compete with it.

Treves has employed Murphy's button in considerably over fifty cases, with results which are certainly satisfactory. The button requires no elaborate preparation, and it is always ready, its introduction is exceedingly simple, and is effected in a few minutes. The two parts of the instrument may certainly jam, but that accident is the result of careless handling. It does not induce a gangrene extending beyond the limit of the button. The two definite and undoubted objections to the button are these: it may be indefinitely retained, and its separation may be followed by contraction of the artificial opening. These two undesirable results are often in close relation to one another as cause and effect.

In the cases of cholecystenterostomy in which he has used the button, Treves has never known it to be retained; and the opening made has not undergone inconvenient contraction. In cases in which the button has been employed in the colon only, though the button was not retained, exceptionally there has been contraction of the new passage.

In examples of gastroenterostomy performed by means of this apparatus, retention of the button for considerable periods, or its absolute failure to appear at all, seems to be the rule rather than the exception.

The explanation of these cases of contraction, whether in the stomach or in the colon, is not far to seek. The button effects an opening between the viscer a by means of pressure gangrene. After-contraction has only occurred in cases in which the upper viscus was much dilated at the time of the operation. It is needless to say that in gastroenterostomy for pyloric obstruction a dilated stomach is met with, and in intestinal anastomosis for stricture the upper segment of the gut is apt to be enormously distended. After the operation the dilated organ contracts, and consequently the newly made hole contracts. A hole in a dilated stomach made by pressure gangrene, and the size of a half-crown, may readily become an aperture the size of a four-penny piece when the distended viscus has gradually contracted. It is therefore very desirable to have the viscer a to be dealt with as empty as possible before the button is introduced. This end is very difficult to secure even to a partial degree. The stomach, for example, in old pyloric obstruction, even when kept washed out for many days, is slow to contract; and if at the time of the operation the viscus be still much dilated, retention of the button and possible inconvenient contraction of the new opening may be regarded as possible.

This association between previous disten-
tion of a viscus and the subsequent contraction of the aperture made in it is, of course, by no means limited to Murphy's button. It applies to nearly every method in vogue for carrying out the operations now under discussion.

Still, in spite of many drawbacks and failures, intestinal surgery has made within the last few years decided and substantial success, but it will fall short of perfection until antiseptic surgery, which so far has penetrated only to the serous covering of the gut, has reached the mysterious and septic lumen which lies within the bowel wall.

THE TREATMENT OF TETANUS BY MEANS OF INTRACEREBRAL INJECTIONS OF ANTITOXIN.

George G. Rambaud (New York Medical Journal, Dec. 17, 1898) was led to try this method of treating tetanus by a contribution from Roux and Borrel, who concluded from a number of experiments that the "tetanic antitoxin, when injected into animals, remains in the blood, whereas the toxin is extracted from it and fixed by the nerve cells. The antidote does not come in contact with the poison, and the two substances, though so near each other, fail to meet. The serum is efficacious against the toxin which is placed under the skin because the greater part of it enters the blood, but it proved powerless against the poison that has already reached the nervous elements."

This is why in man as well as in animals the subcutaneous and intravenous injections so often fail. When they are resorted to, the nervous system has already fixed a smaller or greater quantity of toxin, and while the antitoxin thus administered neutralizes the toxin circulating in the blood and limits the poisoning, it does not reach that which is attached to the spinal or cerebral cells. When the intoxication has advanced too far, the toxin diffuses from one nerve cell to the next, protected from the antidote, and the disease runs its course.

So Roux and Borrel concluded that, in order to bring about a cure in a case of tetanus, the antitoxin must be placed where the toxin is acting in order to preserve the vital portions of the cord before they are affected. Accordingly they treated with intracerebral injections of antitoxin forty-five tetanized guinea-pigs; thirty-five of them recovered. Seventeen others were treated with subcutaneous injections; only two of them survived. Seventeen check guinea-pigs, not treated with the serum, died.

Theory and experimentation agreed. Antitoxin introduced into the brain protects the upper part of the cord when the lower portion is already affected by the poison; but it does not cure the lesions that have already taken place; the contractions existing at the time of intervention persist for some time; and Roux and Borrel state that if the medulla is already poisoned (shown by impaired deglutition, and possibly respiratory disturbances) death cannot be prevented.

The feasibility of the procedure was demonstrated soon after Roux and Borrel had given out the results of their researches. The first case was successfully treated about two months later. A boy developed symptoms of tetanus fourteen days after a crush of the tips of the index and ring fingers. Three days later he was given a subcutaneous injection of twenty cubic centimeters of antitetanic serum. The next day the skull was opened and Roux injected four cubic centimeters of serum concentrated one-half. Three days following twenty cubic centimeters was given subcutaneously, and thereafter in the next five days fifty cubic centimeters in the same way. The patient recovered.

The second case developed without a history of wound. He was given serum subcutaneously on the next day; on the day following he received an intracerebral injection of five cubic centimeters of the concentrated serum. He died on the following day, by asphyxia.

The third case developed tetanus twelve days after injury. On the next day he received an intracerebral injection of six cubic centimeters of concentrated serum, then twenty cubic centimeters subcutaneously. He left the hospital on the twenty-second day following operation.

The fourth case developed tetanus without previous injury. Five days later he received an intravenous injection, which was twice repeated, until on the eighth day the intracerebral injection of six cubic centimeters of concentrated serum was given. This patient recovered.

The fifth patient developed tetanus thirteen days after injury. The following day seven cubic centimeters of the concentrated serum was injected intracerebrally. The next day the patient died, two days after the first appearance of symptoms and fifteen days after operation.

The sixth case developed symptoms nine
days after an injury, and was injected six
days later. He recovered.

The seventh case, an eighteen-year-old boy
working in a stable, exhibited numerous skin
abrasions. Was operated on the day after
tetanus developed. He died forty-one hours
after operation, and eighty-one hours after
the appearance of the first symptom.

The eighth case developed symptoms six
days after a compound fracture of the right
forearm. Two days later he was subjected
to intracerebral injection, and died thirteen
hours after operation, and about seventy-two
hours after first appearance of symptoms.

The ninth case developed symptoms six
days after a compound fracture of the ra-
dius. The following day an intracerebral
injection of six cubic centimeters of con-
centrated serum was practiced, and twenty
cubic centimeters of ordinary serum subcu-
taneously. The patient died the same day.

All these cases are taken from French
journals. The autopsies show that the cer-
bral lesions caused by the injections were
 trifling.

The tenth case developed tetanic symp-
toms eight days after having stepped on a
nail. The cicatrix of the wound was ex-
cised, lumbar puncture was made, and ten
cubic centimeters of serum was injected un-
der the arachnoid, but without success.

Two more cases were reported by Lucas-
Championnière following laparotomy. These
were treated after the new method, but with-
out success, though intracerebral injection
was made within twenty-four hours after the
onset of symptoms.

Rambaud reports a case occurring in the
practice of Robinson, in which tetanus ap-
appeared ten days after a laparotomy, the sub-
cutaneous injection proving powerless; six
cubic centimeters of slightly concentrated
serum was injected into the cerebrum on
the third day of the disease. This patient
recovered from the tetanus, but died eleven
days later of other causes.

Rambaud also cites a case occurring in the
practice of Dr. Johnson. Tetanus developed
seven days after the patient had cut off the
end of his left thumb, while chopping wood.
Two days later intracerebral injections were
practiced. The patient died twelve hours
after operation, and about sixty-five hours
after the onset of the symptoms.

Church reports in full a case of a man who
developed tetanus twelve days after suffering
from an incised wound of the leg. Four days
later the intracerebral injections were prac-
ticed. In addition, because of the suppurat-
ing wound of the leg, twenty-five cubic
centimeters of antitetanic serum was in-
jected into the veins. The following day
several subcutaneous serum injections were
made. The patient recovered.

Reviews.

SYSTEM OF PRACTICAL MEDICINE. By American Au-
thors. Edited by Alfred Lee Loomis, M.D., Late
Professor of Pathology and Practical Medicine in the
New York University, and William Gilman Thomp-
son, M.D., Professor of Medicine in the New York
University. Volume IV: Diseases of the Nervous
System and Mind, Vasomotor and Trophic Disorders,
Diseases of the Muscles, Osteomalacia, Rachitis, Rheu-
matism, Arthritis, Gout, Lithaemia, Obesity, Scurvy,
Addison's Disease.

Philadelphia and New York: Lea Brothers & Co.,
1898.

This volume is the fourth and last of the
series comprising the System, and in general
maintains the high standard of the previous
volumes. To this statement, however, some
exceptions may be taken, as it appears to us
the subjects have not been assigned with the
careful discrimination characterizing the vol-
umes we have already reviewed. Indeed,
in several instances the contributors can
hardly be considered as entitled to speak
with such authority upon the subjects they
have presented as we have a right to expect
in a work of this character.

Again, the reading of the proof does not
appear to have been done with sufficient care
to exclude a number of typographical errors.
Thus, on page 978, the last word of the third
line counting from the bottom of the page is
evidently intended to be "private;" and on
page 977 the cause of gonorrhreal arthritis is
said to be the gonococcus of "Neisser," in-
stead of Neisser.

With the exception of some 170 pages
dealing with a group of miscellaneous sub-
jects the volume, which contains 1082 pages
in all, is devoted to diseases pertaining to
the nervous system. It needs but a glance
at the list of contributors to this portion of
the volume to be assured that the sections
written by Dana, Dercum, Finley, Gray, Mills,
Putnam, Sinkler, and some others may be
confidently turned to for an authoritative
statement of facts. As above suggested,
however, there are a number of contributors
whose names hardly deserve to be associated
with those just quoted. This lack of even-
ness, however, is a fault of most Systems—
we might almost say the fault—but we are
disappointed to find it so accentuated in the volume under consideration, as in reviewing the previous volumes we took pleasure in commenting on its existence to a minimum extent. It is doubtless the keenness of this disappointment that has caused us to make, even in this general way, an unfavorable comment upon this volume, and we would not be understood as seriously detracting from the merit of the book, which in the main is of the highest possible order. Indeed, taken as a whole we consider this System to be the best of those presented to the profession in recent years.

In the volume under present consideration the section devoted to disorders of the mind—contributed by Pritchard, Ford, Noyes, Gray, Pearce Bailey, and Prince—is especially worthy of mention for the very satisfactory manner in which the various subjects are treated. The section is of decided value and has a distinct place in Systems of this character.

To the section devoted to miscellaneous subjects, the addition of which renders the volume more than ordinarily bulky, one of the editors (Thompson) figures as the principal contributor. He is responsible for very thorough and valuable articles upon Rheumatism, Gonorrhoeal Arthritis, Arthritis Deformans, Gout, Lithemia, and Obesity.

To praise too highly the general character of this System would be difficult, and the editors are to be congratulated upon producing a contribution to medical literature that has doubtless already met with the material appreciation that is its due.

T. G. A.

This formulary, about the size of a large visiting list, has a thumb letter index and contains a large number of prescriptions which have been recommended by various practitioners, more or less eminent, for the various diseases under which the prescriptions are grouped.

After the preface there is given a list of the authorities which are quoted, and the name of the authority follows each prescription. The volume closes with a dose table, with a list of incompatibles, of measures, of drugs to be given by atomization, differential tables of the eruptive fevers, and a "surgical remembrancer," which is perhaps the most useful thing in its pages. A diet list and a table for calculating the periods of gestation complete the volume, which, as it has reached the fifth edition in seven years, evidently has proved popular with the profession.

Books, like men, take the place of one another as time goes on, and this volume seems to have succeeded in preempting a large amount of the ground heretofore held by the smaller books on Physiology, as for example that of Yeo and Morrant Baker. If it has done so it has accomplished its task by reason of its valuable qualities, for the book as it stands to-day is perhaps the best manual of modern physiology in the English language.

A very great advantage which it possesses, over and above the fact that it is complete and accurate, is the easy style in which it is written, which makes its reading more interesting than if it were simply a mass of rudely stated facts. The rapid exhaustion of early editions has permitted Dr. Stewart to revise the book frequently and to keep it thoroughly up to the mark. Beside the general text, it also contains information which makes it useful for laboratory experimentation on the part of students.

This little book of 169 pages has been designed by its compiler to supply students with brief information as to the official names, official preparations, doses, and uses of drugs. Taking the drug "ether," for example, its official name is given, official preparations which are made from it are then named, its action is then defined in single terms, and its uses follow. Finally, seven points regarding caution in its use are mentioned, and all this is contained within a space of about two inches of text. As a rule we have not regarded with favor these condensed memorizing manuals, but we shall take pleasure in recommending to our first-year students the immediate purchase of this valuable little guide.

This valuable essay, which was awarded the Boylston prize of Harvard University for 1898, was in part printed in the well known journal Medicine, edited by Dr. Moyer, of
Chicago, and is now reprinted in a large octavo volume of less than 100 pages. As may be imagined from the fact that it won this notable prize, it is a valuable and complete summary of our knowledge of this curious disease, which has been recognized but for a few years. Much of the essay dealing with references to reported cases could not be included owing to the difficulty of printing, but as it stands to-day it is a classical summary of our knowledge concerning the malady.

As may be imagined from the title of this small brochure, it is intended to exploit the advantages of the use of the phonestroscope, and, as is well known, it is claimed that by its use the physician is enabled to outline organs by means of auscultatory percussion and recognize sounds which otherwise would escape his ear. Most physicians have already tried this instrument, and have found that while it is of value in some cases it does not fulfil all the indications which it was hoped it would when it was first introduced, although of course it is a valuable aid to diagnosis.

This revised edition of Buck's well-known textbook covers the modern field of otology even more fully and satisfactorily than did its predecessors in the somewhat restricted list of diseases with which it had to deal. As an entirely new departure may be mentioned the inclusion of the complications incident to infections of the ear. These Buck has classed without hesitation as belonging to the otologist; and has contributed chapters upon Diseases of the Mastoid Process and Neighboring Structures, upon Periophritis and Infective Thrombosis of the Sigmoid Sinus, upon Meningitis, Extradural Abscess, and Abscess of the Brain, which might well serve as models for the writers of surgical encyclopedias.

This work is illustrated by many cases, a method of teaching which does not always accomplish its intended result, and one which in the main should be omitted in books designed to cover an entire subject.

The arrangement of the diseases dealt with, the clearness and directness of the writing, and the rational simplicity of the treatment, are all worthy of high praise, and are important factors in maintaining this work in its position as first of those devoted exclusively to diseases of the ear.

Since the author states that this work is designed to furnish non-professional men with a sufficiently thorough knowledge of matters pertaining to the sexual sphere, medical criticism of it is, perhaps, out of place. It is, however, pleasing to learn that the knowledge which he possesses of this subject has, according to his own statement, been acquired through legitimate channels, and that he has discussed the subject-matter with men of science, doctors, ministers, lawyers, and men about town; also some of it prudently with women.

It would be most unfair to think that the author has made this compilation with any but the best motives. Much of the subject-matter, however, should not appear in a book intended for the laity. Some of the statements made are open to serious criticism.

The book is not sufficiently detailed to gratify the prurient, nor is it so scholarly and accurate that the scientific may learn therefrom. Therefore, to medical men, it is of little use.

This work is not intended as a text-book on renal surgery, but includes three Hunterian lectures: the first devoted to the original progress of renal surgery and the conservative tendency of its recent development; the other two to renal calculi and injuries of the ureter. There is appended a table of cases operated upon, and a final series of cases of calculous anuria.

In his first lecture the author calls attention to the fact that he was the pioneer in the operative treatment of renal lithiasis, having successfully removed in 1880 a mulberry calculus from the undistended, and to the naked eye quite normal, kidney of a young woman. The kidney was exposed
through the oblique lumbar incision, and the stone reached and removed through the renal parenchyma.

In considering the methods of restoring the continuity of the ureter after its complete division, Morris gives preference to that of Van Hook. He states that renal calculous disorders are the most frequent and the most painful of surgical diseases of the kidney. Nephrotomy is one of the most successful and one of the safest of major operations, and cures absolutely, saving the kidney from an otherwise inevitable progressive destruction, and the patient from what at any moment may prove to be imminent danger to life.

The pages devoted to Symptomatology are most important and interesting.

These lectures, representing as they do the results of careful observation of a great number of cases, form a contribution of more than passing interest to the current literature of renal surgery. They are destined to make early diagnosis more certain and to popularize conservative operations, having for their end, and performed in time, restoration to complete health from usually a condition of intolerable suffering.

No writer upon these subjects can carry greater personal weight than does Morris.

Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFORD, M.A., M.D. OXON, M.R.C.P.
LOND.

During the past month death has been busy in the ranks of the profession. First and foremost we have to mourn Sir William Jenner; though at the advanced age of eighty-three, he had in the nature of things for some years lived in retirement from active medical work. His contributions to medical science and literature were not numerous, but all of first-rate importance. Perhaps the best known is his essay establishing the distinction between typhoid and typhus fever, published fifty years ago. It is true he was not absolutely the pioneer of this fact of clinical knowledge, but his paper, based on a minute clinical and pathological study of sixty-six fatal cases, first established the distinction beyond question. His point of departure was the difference in the post-mortem appearances of the bowel, and with this he associated differences in the clinical features of the disease. His only other important work was the Clinical Lectures and Essays on Rickets, Tuberculosis, Abdominal Tumors, and other Subjects. To his observations of rickets the most modern medicine has but little to add. Sir William Jenner was the trusted court physician of Queen Victoria for upwards of thirty years, and held also the blue ribbon of the profession in Great Britain as President of the College of Physicians.

Two other octogenarians have also gone to their rest: Dr. C. J. Hare, a much esteemed physician of the past generation, and Dr. William Munk, Librarian of the College of Physicians, who, outside the sphere of medicine, made several graceful contributions to literature. Better known to Americans will be the name of Professor Kanthack, who has just died at the early age of thirty-five. He leaves behind him a memorial of colossal industry that would have done honor to a man of twice his years.

Medical science has this week been the favored recipient of a princely gift of £250,000 from Lord Iveagh. The sum is to be handed over to the Jenner Institute of Preventive Medicine. This institute is the quondam British Institute of Preventive Medicine, and is the new name it has assumed on acquiring the funds of the Jenner Memorial Committee. In its new home on the Chelsea Embankment the institute should be a national home for bacteriological investigation. Lord Iveagh deserves the thanks of the nation for wiping away a standing reproach against the wealthiest nation in the world for neglecting to make adequate provision for scientific research. It is to be hoped that we may no longer have to cast our eyes oversea for the pioneers of scientific medicine.

Another handsome gift of £20,000 has been placed to the funds of the National Association for the Prevention of Consumption and other forms of Tuberculosis by Messrs. Wernher, Belt & Co., of South African notoriety, for building and endowing a sanatorium for patients of limited means. The Association is thriving steadily under the royal patronage conceded to it.

The School of Tropical Medicine is undergoing the baptism of fire, if we may thus symbolize the rancor of professional jealousy. The difficulty that has arisen is this: The Colonial Secretary very properly was anxious to establish a center for the study of tropical diseases; the natural home for such a
school should have been the Dreadnought Hospital of the Seamen's Society at Greenwich, which has a Branch Hospital of Ease at the Albert and Victoria Docks in East London. The function of this branch is to receive patients on their arrival by sea, and to feed the Greenwich Hospital. Herein is the *casus belli*: Dr. Patrick Manson is adviser to the Colonial Office, and therefore has the ear of the Colonial Secretary, and was also recently appointed physician to the Branch Hospital. Leaving out of count the personal issues of the dispute, the grievance is that the Branch Hospital has latterly evinced a voracious appetite for tropical diseases, and has supplied the mother hospital with an nutritious diet of purely chronic cases of non-tropical maladies; and now the starvation process is to receive official recognition by the establishment of a School of Tropical Medicine in connection with the Branch Hospital. One point is quite clear, namely, that such a school is an imperative necessity; but we do not feel disposed to adjudicate on the question of the preferable site.

At the Edinburgh Medico-Chirurgical Society Dr. Lovell Glland read notes of a case of chronic sulphonol poisoning, in which thirty grains of sulphonol had been taken every night for about six weeks. About a week prior to his death he developed ataxia of all the limbs, lasitude and drowsiness, and then hematomoporyuria. Post-mortem little was to be seen but fatty degeneration of the heart and general stasis in all the organs. Under the microscope could be made out necrosis of the secreting epithelium of the kidney, and early degenerative changes in the liver and suprarenal capsules. Dr. Glland insisted on the presence of the renal changes in both the acute and chronic forms of sulphonol poisoning, and ascribed the fatal issue quite as much to these as to the toxic action of the drug upon the blood. In treating cases of acute poisoning the objects to bear in mind were: (1) to remove as much as possible of the insoluble drug from the alimentary tract; and (2) to promote free diuresis; whilst in the chronic form the free use of alkalis was indicated. Dr. Glland urged that sulphonol should not be given in all cases, especially those where there was constipation, great prostration, or kidney disease. Glland's observations corroborate those of Stern on the changes in the renal epithelium, with the exception that he found no hemorrhagic extravasations. The alleged hemolytic action of sulphonol rests on very insufficient evidence. The moral of Glland’s case seems to be that sulphonol should be regarded as a cumulative poison, and not as a hypnotic agent that can be safely left to the discretion of the patient. Its comparative insulibility tends to make cases of acute poisoning comparatively rare, while chronic poisoning is not infrequent. For this same reason cases of acute poisoning respond more readily to treatment. We have ourselves seen 120 grains inadvertently taken in a single dose by a patient suffering from alcoholic delirium; the only effect was restoration of the healthy mental condition in the course of twelve hours without any toxic effects. Cases of chronic poisoning would undoubtedly be far less common if the bowels were kept well open during administration of the drug; and in this same way the annoying drowsiness that so often persists through the following day might in part also be avoided.

Dr. Ramsay notes a case of serous catarrh of the middle ear produced by the administration of iodide of potassium. The iodide was administered in doses of three grains three times a day, and the symptoms came on suddenly after three days. There were the familiar signs of iodism in discharges from the eyes and nose, but so far as our experience goes catarrh of the middle ear would seem to be a very rare result. Another interesting observation in the same case is that the same dose of sodium iodide was well tolerated, and as is usual in these cases a considerable increase of the dose of the potassium salt also led to subsidence of the symptoms of iodism.

Among minor ailments one of considerable interest has just come under our own notice. We were called to see a young lady, who complained of violent pain in the neck, radiating to the ears and temples; the only other symptom communicated by the patient was dysphagia. Examination of the larynx showed it to be absolutely normal, and there was no reason to suspect disease or injury of the esophagus, as the dysphagia was as great when performing the movement of swallowing as when actually swallowing food. This led us to suspect the thyroid gland, and there was some confirmation of this idea in the fact that menstrual disturbances were prominent. The patient had already exhausted the list of domestic remedies, and we found on inquiry that heat instead of relieving the pain had merely served to intensify it, and induce throbbing in the neck.
There was no visible swelling of the thyroid. Believing that we had to deal with some rapid enlargement of the thyroid, either due to congestion or hypersecretion, we ordered cold applications to the front of the neck, and a mixture of belladonna and sulphate of magnesia. The relief was almost instantaneous. We are aware that the causation of the symptoms is open to question, but this will be much allayed by the information that we have since elicited that another sister of the patient suffered from the same symptoms and had an actual transitory goitre under very much the same circumstances of health. This fact was quite unknown to the patient. The condition would thus be analogous to the acute pain over the lung in some cases of active pneumonia in the absence of pleurisy, and the severe splenic pain in many cases of enlarged spleen—particularly leucocytæmia—in the absence of perisplenitis. How rapidly ice pollicles will relieve the former condition is of course familiar, but we fancy that the same treatment has not been often adopted for the latter condition. We have tried it in two cases of rapid splenic enlargement from leucocytæmia with marked benefit after all other remedies had been attempted. If to this category we may refer the case we have narrated, we have another instance of severe pain due to rapid expansion of the capsular investment of an organ. It seemed worth while to record even so slight a triumph of rational therapeutics, as the relief of even a small pain on rational lines is a substantial addition to the stock in trade of medicine.

At the Royal Medical and Chirurgical Society Messrs. Hutchinson and Barnard brought forward a communication on an improved method of treatment of separation of the lower epiphysis of the femur. They showed by means of skiagrams that it was easy to obtain reduction and also to maintain it by full flexion of the knee so that the heel touches the buttock. There is no difficulty in getting the patient to tolerate the position, and after ten days or a fortnight the limb can be put on a Macintyre splint and subsequently gradually straightened. The accident almost invariably occurs when the knee is hyperextended, so that the epiphysis is drawn forward and the diaphysis projects backward into the popliteal space; at the same time some rotation or twisting of the leg, and corresponding projection of the diaphysial end, is not infrequent. All these points were illustrated by skiagrams, as also a remarkable production of new bone in a comparatively normal manner even when some displacement persisted. This method of full flexion would remove the necessity of forcible efforts at reduction, which of all things were most calculated to damage the epiphysial disk.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Dr. Fournier, professor at the Faculty of Medicine, and physician of the St. Louis Hospital, who is so well known on account of his works on syphilis, gave a lecture recently on the preventive treatment during gestation of hereditary syphilis. The speaker began by saying that he would follow out his usual habit of commencing his course of lectures by examining a question concerning more specially the conduct to be followed by a physician in his practice.

Dr. Fournier examined the following case: A woman is pregnant and her husband syphilitic. Should any treatment be instituted to prevent any syphilitic heredity? Of course, the physician need not hesitate when the woman is already infected with syphilis, but what should be examined is a case where there are no signs of infection. The woman may be pregnant for the first time, nothing can indicate whether she will have a healthy child, and the husband, weighed down by his approaching paternity, and remembering the sins of his youth, asks whether anything can be done to prevent any unfortunate results of his former syphilis.

Much more frequently the case is quite different. The woman has already had two or three miscarriages, or a previous child may have been affected with hydrocephalus.

A treatment should be instituted in such cases; and such conduct is quite rational, as we have learned from Dr. Porak's works on the subject how quickly drugs administered to the mother pass into the child's circulation: Dr. Pinard, the well known accoucheur, once told Dr. Fournier that he had yet to find a case in which a woman had been injured by taking this treatment.

Another thing to be considered is whether this treatment is useful for the child. On this point there can be no discussion. If it is the first gestation, the child is born under good conditions, generally speaking; if there have been a number of miscarriages there is a likelihood that there will be no recurrence
of this. Dr. Fournier cited several examples of this fact, of which the following is an instance: A young man was treated for syphilis and was married two years later. A first child died of congenital debility, a second one suffered from an eruption of syphilides on the fifth week after birth and died. The father consulted Dr. Fournier after this, with his wife, who showed no signs of syphilitic infection, and was just beginning a third pregnancy. A syphilitic treatment of protoiodide of mercury and iodide of potassium alternately was given, and the result was a normal parturition.

Dr. Fournier said that it could be given as a safe rule that when a woman was with child, and this child is in danger on account of the syphilitic taint of the father, a specific treatment of the mother, though she be healthy, is a safeguard of great importance for the child, and should be applied in all such cases.

From what has just been said it should not be thought that an energetic treatment should be followed whenever the father has had syphilis. The physician must decide according to circumstances. There is a great difference between, for instance, a man who contracted syphilis six or seven years ago, who has followed a good treatment and has shown no symptoms since, and a man who has been recently infected, has followed no treatment, and whose wife has had several miscarriages. Between these two extreme limits there is an open field for a variety of cases, and the physician will be called upon to exercise all his sagacity in deciding what is the best course to be followed. In a general way it is better to be cautious and administer drugs where there is some doubt. Once this question is settled, an obstacle presents itself immediately. Is the woman to know for what she is being treated? If the husband has already confessed to her, or intends doing so, the way is plain, but otherwise a physician will be called upon to exercise all his ingenuity to prevent her from learning the reason of the treatment followed. Here the spectre of the belle-mère mother-in-law, so potent in France, is called up. She will want to know why her daughter is obliged to take a lot of pills when she is to have a child, and will remark that, when she had children, no such means were found necessary. Dr. Fournier spoke of a case in point, where he had been called in by Professor Tarnier, and where the mother-in-law had been solemnly assured there was no mercury in those pills.

One day this lady came to him in a fine state of rage, and said to him: "I have had your pills examined by my druggist, and they are full of mercury." This, Dr. Fournier added, should in no wise prevent a physician doing what is best for his patient.

A last point remains to be examined, and that regards the method of treatment. The intervention should be sufficiently rapid—that is, begun in the first period of pregnancy. After the fifth month Dr. Pinard says there is not much hope of producing a good result. Mercury should be used, as being much more active as a preventive, and as an eradicator of any hereditary influence. Moreover, it is much more easily taken than iodides, which so many women cannot tolerate. Protoiodide of mercury is therefore the best preparation and should be given in doses of 0.025 to 0.05 gramme daily. This dose should be taken for twenty days, then a rest of ten days, and so on during the continuance of pregnancy.

The use of guaiacol in the treatment of erysipelas has been tried on adults, but this method has not until recently been employed for children. Dr. Villa, of Genoa, has found it useful in three cases of erysipelas. In his first case the infant, only ten days old, was suffering from umbilical erysipelas, extending from the thorax to the pubis. The temperature was high. The child was given a hot boracic acid bath, and the physician applied all over the affected part and two centimeters further a twenty-per-cent solution of guaiacol in oil, and covered this with a piece of oiled silk. Half an hour afterwards the temperature had gone down from 39.8° to 38.4° C., with abundant perspiration. The next morning the temperature was only 37.5° C., though the area affected had slightly increased in size, notwithstanding a slight change for the better in the color of the skin. The temperature having gone up again in the afternoon to 40° C., a second application was made, and this was done for six days, alternating with the use of balsam of Peru, used to prevent irritation of the skin. Recovery was complete twelve days after the beginning of the affection. In two other cases solutions of thirty or forty per cent were used and proved highly successful. Dr. Villa did not remark any untoward effects from the use of guaiacol.

The 25th of December is the date chosen in Paris for the changing of the services held by the various surgeons and physicians, and at the Beaujon Hospital, for instance, Dr. Anger retired and was replaced by Dr. Bazy,
who has done some work on urinary diseases. Dr. Lucas-Championniere, the great advocate of massage, was called to the Hôtel-Dieu, and Dr. Rigal was replaced by Dr. Lacombe. Dr. Th. Anger, who is specially known for an excellent work he published on cancer of the tongue, was offered a sort of farewell reception in the amphitheater of the hospital, which was garnished with palms and flowers for this occasion. Dr. Tuffier, surgeon of the hospitals, delivered an address, in which he spoke at length of Dr. Anger’s work and of the affection his pupils had for him. Then the surveillante, or head nurse, delivered a short speech in behalf of the attendants in the wards, and then the clou of the whole ceremony. Dr. Ledentu, surgeon at the Neckar Hospital, arose and spoke of the long friendship which had existed between him and Dr. Anger, dating back to the time when they were working together as house surgeons. His speech was most interesting, and towards the end his emotion got the best of him and he embraced Dr. Anger, which sounds very French perhaps to some of my readers, but which was truly touching and not without its own dignity. Dr. Anger answered by a few words, which were listened to with the greatest attention. He said that in his career he had tried to follow out this precept of doing what one could without attracting too much attention, and he prided himself upon always having had good house surgeons to help him in his work; and he ended by describing the death scene of his master, Nélaton the elder, the surgeon of Napoleon III. Nélaton was suffering from Bright’s disease and had had himself placed on a mattress on the floor. He told Dr. Anger to bend over him, and when he was near enough for him to hear what he had to say, he whispered: “Remember, do not much make noise, do good” (“Ne faites pas de bruit, faites du bien”).

At a meeting held by the Society of Surgery of Paris Dr. Quenu spoke of a case of pseudarthrosis where thyroidin was used with good results. The patient was a woman twenty-four years old, who sustained a supracondylian fracture of the femur, with piercing of the skin by a fragment and consequent infection. After three months the fracture was not yet consolidated. Mr. Duval, Dr. Quenu’s house surgeon, gave her thyroidin, and after five days’ treatment she was able to walk with a silicate splint, and she is now quite recovered.

In another case a patient had been operated for exophthalmic goitre, and surgical myxedema had necessitated the use of thyroidin. This patient had later a bimalleolar fracture, and by using thyroidin recovery seemed to be hastened.

Dr. Reclus cited a similar case where thyroidin had proved most successful in a case of pseudarthrosis. On the other hand, in two other cases thyroidin proved of no avail.

**RIGHT INGUINAL HERNIA.**

To the Editor of the Therapeutic Gazette.

SIR: I desire to report the following case, which very recently occurred in my practice:

On November 25 the patient, a woman aged about thirty-five years, called at my office stating that she was suffering from a hernia which had existed for a number of years, but which she had always been able to reduce until about a week previously, when it “came down,” and in spite of all her efforts could not be replaced. Examination disclosed in the right inguinal region a mass slightly larger than a walnut, which was dull on percussion, and pressure on which elicited pain.

An attempt was made to reduce by taxis, but without success. Patient was then sent to her home and told to make hot applications over the tumor until the following day, when under chloroform another attempt was made to reduce by taxis, but this also failed. Believing the mass to be omentum, and no signs of strangulation being present, patient was advised to remain quiet for a few days, meanwhile continuing the hot applications as before.

She was next seen by me on December 5, when the mass had become less tender and seemed to be somewhat reduced in size. Taxis without anesthesia was again tried without result. A spray of ethyl chloride was next applied over the mass until the superficial tissues were frozen. The patient was then placed in the inverted posture and told to take two or three deep inspirations. Upon replacing her on the bed it was found that the mass had been partially reduced, and very slight manipulation caused it entirely to disappear.

While this case does not, of course, prove the superiority of any particular method, it does serve to emphasize the fact that a hernia that cannot be reduced under anesthesia will sometimes yield to simpler means.

THE CORRECTION OF DEFLECTIONS OF THE NASAL CARTILAGINOUS SEPTUM, WITH A REPORT OF SIX CASES SUCCESSFULLY TREATED BY THE ASCH OPERATION.

BY P. S. DONNELLAN, M.D.,

Graduate of the Royal College of Physicians and Surgeons, Ireland; Fellow of the College of Physicians of Philadelphia; Laryngologist to St. Mary's and St. Agnes' Hospitals, Philadelphia.

Until within a comparatively recent time our knowledge of the functions of the nose was limited to the essential facts that it was the organ of smell and that it provided an entrance for air into the larynx when the mouth was closed. But with the advances made in the study of rhinology it was discovered that the nose performed important duties besides those I have mentioned, and that any marked deflection from its normal structure was attended with corresponding impairment of function and the development of pathological conditions, not only in the nose, but in the nasopharynx and larynx.

Boch has shown in his important studies on the physiology of nasal respiration that the temperature of the inspired air was raised about forty degrees in its passage through the nasal chambers. Lennox Browne has drawn attention to the part taken by the

nose in voice production, particularly of the vowel sounds, and declares that phonation and articulation are not only impaired in the victims of nasal obstruction, but that in this condition singing in the falsetto register is impossible.

In addition to the impairment of the physiological functions of the nose by obstruction of its chambers, many pathological conditions may be developed, such as postnasal catarrh, chronic pharyngitis, enlargement of the tonsils, chronic laryngitis, and bronchitis. Marked deflections of the septum play an important part in the production of these conditions, as is well understood, and it is the duty of the rhinologist to correct them by appropriate surgical measures.

That the septum is rarely perfectly symmetrical is shown by the researches of Harrison Allen and others, who found in an examination of over two thousand skulls marked septal deviation existing in about seventy-five per cent. These researches referred only to the bony septum and did not include deflections of the cartilaginous septum, which as a rule is alone affected. A deflection may involve either the bony or cartilaginous portions, or both. Sometimes it is sigmoid in shape, being convex below and in front and concave above and behind—the opposite condition existing in the other nostril. Usually, however, the deflection presents but a single curve, which may be rounded or angular, and generally occurs along sutural lines.

In two of my cases the septal cartilage was dislocated from the perpendicular plate of the ethmoid and from the vomer, completely obstructing the nostril and deflecting the tip of the nose.

Nearly all deflections are the result of traumatism occurring in childhood, when falls and blows on the nose are not uncommon, and for obvious reasons are seen far more frequently in the male than in the female.

The symptoms are those of stenosis, postnasal catarrh, dryness of the mouth and pharynx, and in advanced cases chronic laryngitis and bronchitis may occur. Such patients are liable to colds in the head; they frequently develop hay-fever if exposed to the exciting cause, and many cases of catarrhal deafness have their origin in septal deflections. In this connection it may be worthy of mention that the passage of a Eustachian catheter is attended with great difficulty, and in some instances is impossible where marked deflection of the septum is present. From the above statement it will readily be seen that the correction of septal deflections is imperative if we wish to restore the physiological functions of the nose and relieve the varied pathological conditions to which they give rise.

It is not my intention in this article to describe the various surgical procedures which from time to time have been devised for the correction of cartilaginous deflections, but, as indicated by the title of my paper, to draw attention to the value of the operation of Asch, of New York, in dealing with such cases. It was first performed by him about sixteen years ago, and the details of six cases he operated on with success were communicated by him to the American Laryngological Association at its meeting in 1890. Emil Mayer reports two hundred cases of septal deflection successfully treated by the Asch operation in the New York Medical Record of February 5, 1898.

A set of special instruments have been devised for the operation, which are reproduced in the illustrations. Fig. 1 shows a blunt dissector or separator for the purpose of separating any adhesions which may exist between the deflected septum and the lower turbinal on the affected side. Fig. 2 shows the special scissors used. As will be seen, it is a powerful instrument with slender prongs curving outward so as to embrace the septum, and terminating in two blades, one of which has a triangular-shaped cutting edge, the other being blunt. A scissors with angular blades is shown in Fig. 3, and is used in cases where the deflection lies near the floor of the nose, when the straight scissors would be useless. A compressing forceps is shown in Fig. 4, and is used to compress the septum in place after it has been incised by the scissors. It is somewhat like the Adams forceps and fulfils the same object. Fig. 5 shows the vulcanite hollow perforated splints of Asch, used to keep the straightened septum in place after operation, and Fig. 6 its modification suggested by Mayer, which is more oval in shape. These are made in different sizes to suit individual cases.

The operation is performed with strict antiseptic technique and is best done under a general anesthetic, unless this is contraindicated, when cocaine anesthesia may be used. The patient is prepared in the usual way; and the nasopharynx is first sprayed with Dobell’s solution and afterwards with peroxide of hydrogen, the object being to
make the nasal chambers as sterile as it is possible for a mucus-secreting cavity to be. All the instruments, including the vulcanite nasal splints, are sterilized by boiling.

The patient having been placed on the table and etherized, the head is kept low so as to avoid the danger of blood entering the larynx. When complete anesthesia has taken place, the operator passes the blunt dissector into the obstructed nostril and detaches the septum from the adjacent turbinate. He then inserts the scissors—the cutting blade in concave side of the septum and the blunt blade over its most convex portion. The blades being parallel with the floor of the nose, they are firmly closed and the septum is cut through. The scissors is now withdrawn and reinserted, this time pointing towards the root of the nose so as to make, if possible, an incision crossing the first at right angles. The septum having been cut through in the manner I have described, the compressing forceps are inserted well back in the posterior nares, so as to embrace the four segments of the septum, they are firmly closed, and the deflection is corrected. When bleeding, which is usually very slight, has been controlled by ice compresses and by douching of the nares with peroxide of hydrogen, the vulcanite splints are inserted, a large one in the naris previously deflected and a smaller one on the opposite side. The patient is put to bed, given a sedative if needed, and kept on a light diet. The nostrils are sprayed with Dobell's solution every four hours, and the day succeeding the operation the smaller splint is removed, the larger one being allowed to remain until two days later, when it is removed to be sterilized, and is then reinserted. The patient is discharged from the hospital on the fourth day and is instructed to report daily to have the splint sterilized and reinserted.

The patient is shown how to remove and insert the splint himself, which he does, and having worn it for almost a month he di
cards it. The septum is then usually found to be perfectly straight, and no further treatment is necessary. Occasionally, however, a small spur may need removal with the Bostwick saw or cutting forceps.

The following report of six cases of deflection of the cartilaginous septum in which I performed the Asch operation successfully will serve to illustrate its usefulness in correcting the deformity:

Case I.—Edward B., aged sixteen years, presented himself at my clinic at St. Agnes Hospital on February 2, 1898. When five years old he fell and fractured his nose, the tip being turned to the right. Since then he had suffered from complete obstruction of left nostril with severe postnasal catarrh, and two years previous to his visit a purulent otitis developed with much impairment of hearing.

Examination showed complete deflection of the cartilaginous and bony septum to the left, with adhesions between it and the left lower turbinal. On March 10 I performed the Asch operation under ether, but as the compressing forceps did not engage all the segments of the cut septum, a second operation was done two weeks later, with complete success, the boy a month afterwards being discharged from the dispensary with a perfectly straight septum and relief from his postnasal catarrh.

Case II.—Bessie, aged six years; first seen at St. Agnes Hospital, March 22, 1898. When fifteen months old she fell from a chair and fractured her nose, which was tilted to the right. Her mother stated that the child was a mouth breather since that time, and noticed a projection from the left nostril, which was treated by the family physician as a nasal polypus. On examination I found the alleged polypus was the left side of a very deflected septum which completely obstructed the nostril. On March 26 the Asch operation was done under ether, the patient making an uneventful recovery, the septum being perfectly straight and the tilting of the nose removed.

Case III.—Ellen C., aged nineteen years, pupil nurse, had suffered from obstruction of left nostril with postnasal catarrh and muffled voice for five years. There was no history of injury to the nose. Examination showed the sepal cartilage deflected to the left, causing complete obstruction in the nostril. The Asch operation was done under ether on April 16, 1898, and the result was entirely successful. Six months later it was found that the nasal tone of the patient's voice had disappeared and its timbre had greatly improved.

Case IV.—Judge E., aged sixty-two years, had suffered for several years with obstruction of the left nostril, which became complete when driving or bicycling in a strong wind. He also complained of postnasal catarrh and dryness of the throat. Examination showed sigmoid deflection of the cartilaginous septum to the left with an adherent lower turbinal. There was marked chronic pharyngitis. The Asch operation was performed under ether at St. Agnes Hospital on March 18, 1898. There was considerable hemorrhage on account of the plethoric condition of the patient, but it was readily controlled by iced compresses and syringing the postnares with peroxide of hydrogen. The patient made an excellent recovery, with a straight septum and relief from his nasopharyngeal symptoms.

Case V.—Miss H. I., aged nineteen years, was first seen in June, 1898, with the following history: Four years ago, while entering a dark room, she struck her nose against an open door, and a violent attack of epistaxis followed. Her attending physician told her that the bridge of her nose was fractured and that an operation would be required to straighten it when the swelling had subsided. Following this accident she suffered constantly with nasopharyngeal catarrh and nasal obstruction, the latter being most annoying when she rode her bicycle. On examination I found the cartilaginous septum dislocated to the right, causing complete obstruction in that nostril. I performed the Asch operation under ether on June 20 at patient's residence, and the result was very gratifying.

Case VI.—Miss K. C., consulted me on October 14, 1898, for persistent nasal obstruction in right nostril, accompanied by severe neuralgic pains in right side of head and constant weeping of the right eye. The trouble was of two years' duration, and as far as patient knows she never had any injury to her nose. Examination revealed an angular deflection of the cartilaginous septum, which pressed on the right lower turbinal, causing obstruction to the nasal duct. The Asch operation was performed under ether on October 27, and the patient made an uneventful recovery. Two months later she reported the neuralgic pains had disappeared, while examination showed a straight septum and a nasal duct unobstructed.
JEQUIRITY IN THE TREATMENT OF
GRANULAR CONJUNCTIVITIS.*

BY WILLIAM M. SWEET, M.D.,
Associate in Ophthalmology, Philadelphia Polyclinic; Instructor in Ophthalmology, Jefferson Medical College;
Ophthalmologist, Phoenixville Hospital.

Shortly after the publication in 1882 of the first paper of Dr. L. De Wecker, of Paris, on the use of jequirity in granular conjunctivitis and pannus, the treatment was tried in all the large ophthalmic clinics of the world, and the descriptions of the cures effected were of the most glowing character. The remedy was recommended by De Wecker as a substitute for the method of inoculation with blennorheic pus, a form of treatment that was sometimes employed in obstinate cases of granular conjunctivitis, but which was followed occasionally by destructive inflammation of the ocular structures. After jequirity had been employed for some time, numerous cases were reported of extensive reaction following its use, with the production of diphtheritic inflammation and the presence of perforating ulcers of the cornea.

With a view of determining the experience of investigators in this country in the treatment of granular conjunctivitis with jequirity, Dr. H. Knapp† published in 1884 a series of papers from various clinical observers, which proved the value of the new remedy, but also showed its dangers. In summing up his own experience, Dr. Knapp stated that jequirity cured trachoma more quickly but less safely than other remedies; that its action was neither uniform nor always controllable; that it caused more or less atrophy of the conjunctiva and the formation of cicatrical tissue; and that the greatest danger consisted in the occasional development of severe diphtheritic conjunctivitis and more or less extensive destruction of the cornea. One of the reports of the series mentioned, that of Dr. Hasket Derby, of the Massachusetts Eye and Ear Infirmary, showed twenty-four cases treated, of which number seven were followed by corneal ulceration. With the mass of testimony unfavorable to the use of the remedy, it was naturally soon abandoned in most clinics, and at the present time is only occasionally employed. Recently Dr. Wm. Cheatham‡ has reported a case of trachoma cured by weak in-

THE USE OF BENZOSOL IN CHRONIC PULMONARY TUBERCULOSIS.

BY JULIUS L. SALINGER, M.D.,
Chief of the Medical Out-Patient Department, Jefferson Medical College Hospital, Philadelphia; Physician to Philadelphia Hospital.

It has been the routine practice in the outpatient medical department of the Jefferson Medical College Hospital to treat the patients suffering from chronic pulmonary tuberculosis by the internal administration of creosote in ascending doses. While this treatment was followed by uniformly good results, the repugnance of the patient for the smell and taste of the remedy was in the great majority of the cases difficult and often even impossible to overcome, especially in those cases complicated by anorexia, nausea, vomiting, eructations, and general gastric disturbance. It occurred to the writer that if a remedy could be found that would have the same beneficial effect as creosote, without the objectionable elements (taste, smell, etc.), it would be doubly beneficial to the patient. With this end in view benzosol was given a fair and unbiased trial. The remedy was given alone; no other medicament or tonic was used in combination with the benzosol. Five-grain doses, and in some instances ten grains, were administered three times daily. The benzosol was given in the form of powder or compressed pill. The following table, which was kindly prepared by Dr. C. A. Holder, assistant demonstrator of clinical medicine, shows the result. These investigations were carried on for over six months.

Benzosol is a synthetical preparation, and is a combination of benzoyl and guaiacol. It is free from cresol bodies. It is a colorless crystalline powder, with a slightly pungent taste, and is not soluble in water. It is said to contain fifty-four per cent of guaiacol.

The remedy is unaltered by the gastric secretion, requiring the alkaline juices of the intestine to liberate the guaiacol and the benzoic acid, into which the drug is broken up when absorbed. It has the great merit over both its constituents that it does not affect digestion, and that it is odorless and tasteless.

No attempt is made to claim for benzosol that it is a specific in chronic pulmonary tuberculosis. The fact may, however, be emphasized that it has all the advantages of creosote without its drawbacks. No com-

special attention; and no membranous exudate formed in a single instance, nor has the cicatrization been greater than would be expected with the usual forms of treatment. It would therefore seem that purulency, which was the effect aimed at in the early use of the drug, is not an important factor in the cure.

In the one case above referred to there existed at the time the treatment was begun considerable conjunctival secretion, with marked pannus and several shallow corneal ulcers. The weak infusion seemed to aggravate the conditions present, and was at once stopped.

One of the patients benefited by the treatment had a trachomatous pannus of both eyes which had existed for a long time, and which failed to improve by the usual forms of treatment. The vision was so poor that it was necessary to lead him to the clinic. After two months of treatment with jequirity the pannus disappeared, leaving a slight haze of the cornea, and he is now able to read large print.

In preparing the infusion, cold water is placed upon the powdered seeds in a loosely corked bottle, and after macerating for twenty-four hours is filtered and used. The infusion should be made fresh each time it is used, as it soon decomposes and becomes inert. De Wecker states that the infusion may be made with cold water three hours before use, and that the strength is as great as when macerated for twenty-four hours.

The first application is from two to four grains to the ounce, a cotton mop soaked in the infusion being freely passed over the everted lids. The application is repeated every second or third day, being increased in strength one grain of the powder each time. As soon as a slight discharge appears the treatment is discontinued for about four days, and is then begun again with the next stronger infusion. In some cases an infusion of twenty grains to the ounce has in this way been employed without causing any severe inflammatory symptoms.

From the results achieved by the use of jequirity in weak infusions, gradually increased in strength until the susceptibility of each case is determined, I believe the remedy is one of the most valuable that we have for the treatment of trachoma, especially when associated with pannus, and that employed in this way it is devoid of danger to the structures of the eyeball or lids. It is not indicated in acute trachoma, nor in cases in which there is much purulent secretion.

Note.—Tubercle bacilli were present in all cases.

plaint was made by any of the patients on account of the taste. The only objection to benzol (if this be an objection) is the fact that it is more expensive than creosote, and this in hospital practice must be taken into consideration. In two cases of tubercular peritonitis no result was obtained by the prolonged use of benzol.

The cases most benefited by benzol were those in which, besides the pulmonary lesion, there were gastrointestinal symptoms. The exhaustive diarrhea of phthisis was usually promptly relieved by its use.

In a few cases of simple acute intestinal catarrh benzol proved very effective, especially in the summer diarrheas of children of bacterial origin, where it became necessary to prevent fermentation.
CAMPHORIC ACID FOR NIGHT SWEATS.

BY H. R. Coston, M.D.,
Fayetteville, Tenn.

The night sweats which accompany or follow many diseases, and especially tuberculosis, are so exhausting to the patient and often so resistant to all forms of treatment that any remedy which will give relief should be brought prominently to the notice of the profession.

Of the many remedies which I have tried camphoric acid gives the best results. I will relate briefly a few cases:

CASE I.—J. M. W., aged fifty-two, suffering from chronic pulmonary tuberculosis, had very severe and exhausting sweating, beginning as soon as he went to sleep, and from which he would awaken drenched with sweat and almost collapsed. I gave him half a drachm of camphoric acid in half a glassful of sweet milk one hour before bedtime. That night he had no sweat; and strange to say has had none since, although more than a year has elapsed.

CASE II.—J. B. R., aged twenty-five. Following an attack of acute rheumatism he had night sweats so badly that they began to tell severely on the system. A single dose of thirty grains of camphoric acid stopped them for a week, when the dose had to be repeated.

CASE III.—James McK., aged twenty-four. Acute pulmonary phthisis; last stage. His mother reported that he was drenched in perspiration every time he went to sleep. Camphoric acid in half-drachm doses controlled this until his death, giving much relief.

I have used the remedy in many other cases and always with the very best results. After the defervescence of fever in typhoid cases, when the nervous centers are in so debilitated a condition that they do not properly innervate the body during sleep, the patient loses more from the profuse perspiration than he gains by the sleep. In these cases a twenty- or thirty-grain dose of camphoric acid will act so well that no sweating will occur and the patient will awake refreshed rather than exhausted.

It is not a remedy whose beneficial effects last only a few hours, for as a rule I have not had to give the second dose for several days and do not remember ever to have had to repeat it on the same night.

The remedy should be given an hour be-

fore the sweating is expected to begin. The dose which I usually give is half a drachm, but this may be increased or repeated if need be. It is best given dry on the tongue and washed down with half a glassful of water or sweet milk. It does not dissolve in water, and the alcoholic solution is so intensely bitter that I never use it, as very few patients can tolerate it.

THE RELATION OF EARLY DIAGNOSIS BY MEANS OF THE ROENTGEN RAY TO THE RESULTS OF NEPHROLITHOTOMY.

BY CHARLES LESTER LEONARD, M.D.,
Skiagrapher to the University Hospital; Assistant Instructor in Clinical Surgery, Philadelphia.

The difficulties met with in differentiating between calculous nephritis and other renal disorders render it in some cases utterly impossible to establish a positive diagnosis by ordinary means. That this is recognized by eminent authorities is shown by the frequency with which they resort to exploratory operations. They have most certainly rendered inestimable service, and we are indebted to these operations for a clearer understanding of many of the pathological conditions that involve the kidney. If, however, they are imperfectly performed they may be very misleading, as a stone overlooked would tend to render the diagnosis even more obscure.

However valuable this mode of examination may be in cases where renal calculi are suspected, there are many cases in which the symptoms are not sufficiently developed to warrant its employment before the calculus has reached a large size and produced irreparable injury. Smaller calculi are capable of disorganizing, disintegrating, and destroying the renal tissues long before they make their presence known through definite symptoms.

How many cases go undiagnosed it is impossible to determine, but it is certain that numerous patients die from impacted calculi and subsequent anuria, while post-mortem examinations have frequently demonstrated the total destruction of one kidney as the unsuspected result of renal lithiasis. These patients have, at some time, had symptoms that would suggest the possibility of stone, yet they have not been marked enough to make it probable or operation justifiable,
while the pathological process present has been sufficiently severe to destroy the entire kidney. Such cases illustrate the difficulties in the way of diagnosis, and point to a deficiency in diagnostic methods.

Under these conditions it is little wonder that surgeons looked to the Roentgen ray with the hope that it would aid in solving this problem. Early experiments in this direction showed, however, that although it might be possible to detect the denser calculi through the lumbar region, the light that would penetrate that area would also penetrate the less opaque forms. Thus it was that the presence of a shadow of the calculus in a negative proved it to be present, while the contrary was not true, for one of the less opaque forms might have been penetrated though present.

To solve the problem it was necessary to produce rays capable of passing through the lumbar region and differentiating between its lesser densities. This has been accomplished, and an improved technique and apparatus make it possible to differentiate between the density of the kidney itself and the surrounding structures, so that we are certain that in a negative in which this amount of detail is present no calculus of any variety can escape detection.

The technical difficulties surrounding the production of such negatives were very great, for in each case the density of the individual patient must be correctly judged, and the length of exposure and quality of x-ray employed so adjusted that the light, while penetrating the lumbar region, will differentiate between its lesser densities. Overexposure or too powerful penetration will obliterate all structures, while underexposure or too "soft" an x-ray will fail to penetrate the region sufficiently. The length of the exposure varies from five to twenty minutes, according to the physique of the patient, the condition of the tube, and the quality of the current.

A series of cases that have stood the clinical test of operation have demonstrated the mathematical accuracy and correctness of this method of diagnosis. Its effect upon operation is threefold: it renders operation possible in the early stages of the disease, when recovery is rapid and impairment of function slight; it makes the operation complete, and hence increases its efficiency and value; it prevents operation without full knowledge of the condition of the other kidney as regards calculi.

The great value of this method of diagnosis is seen in cases where the symptoms are so indefinite that it is impossible to differentiate between disease of the kidney and that of some neighboring organ. This is especially true of disease of the right kidney, as its proximity to the hepatic and appendiceal areas renders the diagnosis more difficult where the symptoms are masked or but few symptoms are present. The value is still greater in making the diagnosis between calculous nephritis and other inflammatory conditions of the kidney. They are so similar in their symptomatology that it often requires the whole group of symptoms of any one condition to make the differential diagnosis positive. It is, however, true of calculous disease that it may exist for a long time before enough symptoms show themselves to make an absolute diagnosis possible. In some cases calculi attain large proportions, and, as has been stated, post-mortem examinations have frequently shown that calculi have produced the total destruction of a kidney without their presence having been more than suspected.

I have seen operation demonstrate the correctness of the Roentgen ray diagnosis in a case where a history of indefinite lumbar pain and a slight amount of albumen and pus were the only symptoms that led to the suspicion that a small calculus might be present. The calculus removed was very small, but it had caused slight disability for a number of years and had wrought considerable injury to the renal tissues. The effect of such an early diagnosis was seen in the relief from pain and a depressing pathological condition, while the removal of the cause, before the function of the organ had been materially injured and while its reactive and recuperative powers were sufficiently intact, insured a rapid and complete recovery.

How fallacious an exploratory nephrotomy may be can be readily judged from the impossibility of detecting even a moderately large stone in a kidney, even when it is upon the post-mortem table. It is admittedly impossible to determine the presence or absence of renal calculi by needling, and exploratory incision into the substance of the kidney itself is considered by some surgeons to be unjustifiable; while it has not infrequently happened that a calculus has escaped detection even after the finger has been introduced into the pelvis of the kidney. This is especially liable to happen in cases where there are multiple calculi, the surgeon being readily
content with the removal of one large calculus. The Roentgen ray is very valuable not only in definitely deciding that a calculus is present, but also in determining whether one or more are present and what their relative location is. In three of my cases multiple calculi have been found. In any one of them the surgeon would have been content with the removal of one calculus, as the others were in one case encysted, and in another situated in a deep diverticulum of the pelvis, where persistent search, born of the knowledge that they were there, was required to find them. If they had not been shown by the sialograph the result of the nephrolithotomy would have been incomplete, the remaining calculi continuing the destructive process; and a supposedly complete operation would only have served to render the condition more obscure. The value of the completeness of this form of diagnosis cannot be overestimated. It adds mathematical accuracy and precision, even where the symptoms of renal calculus are almost self-evident, making it possible to remove the most minute calculi and to perform a complete operation.

The nature of renal lithiasis makes it impossible, no matter how complete the symptoms, to determine by any other method of diagnosis whether one or more calculi are present, or whether one or both kidneys are involved.

Late writers have suggested that double exploratory nephrotomy be performed in order to determine the condition of both kidneys. This suggestion shows that this condition is not only possible but probable in many instances, and it has been frequently demonstrated in operating and in post-mortem examinations. The Roentgen ray is a ready solution of this problem, and all cases of suspected calculus should have this complete method of examination before the risks of operation are undertaken. I have seen the demonstration of this application of the Roentgen ray.

To summarize:

1. Recent improvements in apparatus and technique have made it possible to penetrate the lumbar region and yet differentiate between the lesser densities.

2. Sufficient detail can be obtained in the negatives to render it absolutely certain that no calculus can escape detection.

3. The absolute diagnosis of the presence or absence of calculi can therefore be made.

4. This method of diagnosis renders the detection of calculi possible even where the symptoms are so masked or wanting as to render it impossible in any other way.

5. The mathematical accuracy of the diagnosis renders the detection of multiple calculus possible and their removal certain. It therefore insures a complete operation.

6. It is the only method of examination that can positively determine before operation whether only one or both kidneys are involved.

7. The employment of this method of diagnosis should make intervention at an early period possible, and tend to better the results obtained by nephrolithotomy.

APOCHYNUM CANNABINUM.

BY G. H. MAYHUGH, M.D.,
Westerville, Ohio.

The numerous letters appearing in THE THERAPEUTIC GAZETTE during the year 1898, and the regular communications found therein, regarding Apocynum cannabinum, and the incidental reference made to Apocynum androsaemifolium, have been read with more than ordinary interest by me; and while I am not unmindful that the discussion of the matter has been unusually full and extended, the desire is irresistible to make a few further observations upon the subject. In the first place, it is proper that notice be taken of some statements in the very elaborate and, it is proper to add, valuable paper, judging from a clinical standpoint, appearing in the November issue, from the pen of Dr. T. S. Dabney. He states that Apocynum cannabinum is "a remedy scarcely mentioned in works on therapeutics and materia medica," and says: "Bartholow, Waring, Ringer, Hare, and H. C. Wood make no mention in their works on materia medica of this remedy." The Doctor's last statement is no doubt strictly true, and reference is here made to it only to deplore the fact. Scholastic and creedal exclusiveness should have no place in science anywhere, much less in that branch which is of such vital importance to sick and suffering humanity, and to nothing else than that can the omission, not only of this agent but of many other indigenous remedies equally valuable and potent for healing, be attributed. It is greatly and sincerely to be hoped that future editions of these otherwise very valuable works will enhance their usefulness by adding several well known and valuable native drugs.
The reason Dr. Dabney assigns for the "expurgation of apocynum practically from the materia medica," as he puts it, is certainly not because, as he says, a reliable preparation of the drug was not obtainable—indeed, easily accessible—for at least two of the largest and most reliable drug houses in the West have for very many years had on the market a thoroughly representative product of this drug. A desire to avoid tincturing this communication with commercialism forbids the mention of these firms by name. These preparations have had a large use at the hands of hundreds of physicians.

Now, as to Dr. Dabney's first statement that it is "a remedy scarcely mentioned in works on materia medica and therapeutics," he is certainly likewise in error, and the suggestion is here ventured that the Doctor's reading has been, like the works of the authors whom he so justly criticizes, too narrow in its scope, and has not taken in the works of various "irregular" schools of medicine. The Thomsonian Materia Medica (in 1841 in its thirteenth edition); The Physico-Medical Dispensatory; King's American Dispensatory; The Physico-Medical Materia Medica; Coe's Concentrated Organic Medicines; Locke's Materia Medica and Therapeutics; Scudder's Specific Medicine—all these describe fully Apocynum cannabinum, and point out its indications and uses.

Of course, Dr. Dabney's remark is strictly true when applied to the works of "regular" medical authors, but though a "regular" graduate myself, love for the truths of a broad and liberal science of medicine leads me to recognize and make use of the fact that there have been, and are, many earnest workers in the fields of materia medica, outside of the ranks of "regular" medicine, who have written many valuable and scholarly works worthy of careful study by all medical men.

Dr. Dabney deserves great credit for his effort to get his colaborees to give deserved attention to this drug, just as there is, likewise, praise due the late Dr. Black, of Newark, Ohio, in discovering (?), some fifteen years ago, that Euonymus atropurpureus was a valuable agent, and urging its use. Dr. Phares, of Newtonia, Miss., in 1866, made a like revelation (?) regarding Viburnum prunifolium, and his efforts deserve commendation.

The hope is indulged that Dr. Dabney will fully succeed in his efforts to induce the authors of "regular" medicine to give this remedy its deserved recognition.

In the second place, permit a few words as to the preparation of this drug which is most reliable. I have used with equally good results both the "specific" and "normal" tincture, and in all those cases where there were the indications for the drug, namely, a weakness of the vessel walls, allowing transudation into cellular tissue, or a weak heart and low blood-pressure, it has uniformly given excellent results. In the hands of many careful clinicians the resinoid, apocynin, gives results just as good. In a clinical lecture delivered before his class in the Cincinnati College of Medicine and Surgery, and reported in the June, 1898, issue of the Alkaloidal Clinic, Prof. John M. Shaller describes his use of apocynin in three cases, in which it gave rapid relief. The first was that of a young man, aged twenty-five years, who had had albuminuria for over two years: "There were painful and marked pulsations in the veins of the neck, no pulse at wrist, extensive edema, dilatation of right heart, with inharmonious action of the valves, embarrassed respiration, and highly albuminous urine."

Apocynin, in doses ranging from one-sixth grain every two hours to one-third grain as often (fourth day), was given, the only other agent given being strychnine arsenate—one-fortieth grain three times a day. All abnormal symptoms rapidly disappeared. His second case was one of edema of feet and legs, the result of a weak heart and low blood-pressure, in a patient aged seventy-six. Under apocynin the patient got well rapidly.

The third case was one of mitral regurgitation with edema of feet and legs, in a man of fifty. Two one-twelfth grain granules of apocynin were given every two hours and relieved the edema within a week. Apocynin has an advantage over digitalis in these cases especially, in that it has a cathartic effect also, and catharsis is nearly always desirable. It never disturbs the stomach, if given in small doses, as digitalis does so often, but is really tonic thereto. Dr. Shaller advises the use of at least one-fourth grain to begin with, given every two hours, gradually increased after three days until effect.

Certainly apocynin, given in the conditions pointed out above, has an established reputation and is as surely a specific for the indicated conditions as is quinine for malaria; and the extended discussion of this agent in these columns cannot but be of very great value to the large body of medical men who have not heretofore used this potent drug.

TREATMENT OF HEMOPTYSIS.

There are certain conditions met with by the physician in active practice which he must admit as being very distinctly incurable—at least so far as any medical or surgical interference on his part is concerned. There are few of these which are more beyond his control than the condition which is known as pulmonary hemorrhage, which like all concealed hemorrhages, in the sense that we cannot get to the bleeding point, is peculiarly dangerous to the patient who is suffering from it. As a matter of fact it is not a reflection upon the ability of the medical man that this is the case, yet there are few of us that have met with these patients who have not felt a necessity for active interference in their behalf. At the present time the treatment that is most frequently carried out is probably the administration of ergot internally and the use of morphine and atropine hypodermically, while many physicians also administer tannic acid, gallic acid, alum, and even common salt, in the hope that they may be able to aid in the formation of a clot which will plug the bleeding vessel.

The mere taking of salt in the mouth is probably without any influence whatever upon the bleeding, and only when a sufficient quantity of it is swallowed to produce nausea, and therefore a diminution in circulatory activity, can it exercise even an indirect influence over the condition which we are attempting to combat. Tannic acid is so slowly absorbed, and has such feeble counteracting influence upon blood-vessels, that it probably rarely if ever does good when given by the mouth, and alum, aside from the nausea which it may produce, is equally useless.

Much interest centers around the use of ergot under these circumstances, and there seems to be little doubt that its general employment is productive of no good. In the first place, ergot, by its influence upon the vasomotor system, causes a rise in arterial pressure, which, if the hemorrhage comes from an eroded artery, must necessarily increase the flow of blood; and further, it can only check hemorrhage when its influence is exerted upon the muscular coats of blood-vessels which supply the capillary network which is leaky. In other words, if the hemorrhage comes from a blood-vessel of any considerable caliber, ergot is not only useless but probable harmful, and can only do good when used to check oozing hemorrhages from capillary areas, from which it cuts off the blood by contracting their supplying blood-vessels.

What, then, are the measures which should be introduced by the physician who is called upon to treat these grave complications? The reply to this question depends to a certain extent upon the exact cause of the hemorrhage, for hemoptysis is not by any means invariably caused by pulmonary tuberculosis, although this disease may be its most frequent causative factor. If the hemorrhage takes place in a person advanced in years, with high arterial tension and atheromatous blood-vessels, it is our duty to determine whether the blood which is coughed up arises from engorged vessels, which are congested because the right side of the heart is too weak to pump blood through the lung. In such a case digitalis and similar remedies are of advantage, and the hemorrhage in such cases is usually small in quantity and perhaps only stains the sputum.

On the other hand, if associated with an atheromatous condition of the blood-vessels
we find a high arterial tension, then nitroglycerin may be the obvious remedy, since by decreasing tension it will tend to diminish the leakage of blood.

If the heart is hypertrophied it may be necessary to administer in addition small doses of aconite, while on the other hand, if it is feeble, the well known combination of digitalis and nitroglycerin may be needed. So, too, in cases of hemoptysis arising from valvular disease of the heart, it may be that the proper administration of cardiac medicaments will cause an arrest of the present hemorrhage and prevent future ones from occurring.

If the cause of the hemoptysis be tuberculosis of the lung, the proposition is quite different, and the treatment, it seems to us, must depend largely upon the general condition of the patient and the freedom with which the blood seems to be flowing. When the hemorrhage is free there seems to be little doubt that a hypodermic injection of morphine in a dose of a quarter of a grain is the best routine method of treatment, because it does something towards relieving the mental anxiety of the patient, and, what is more important, it checks the incessant cough and thereby permits the clot to form in the leaking vessel. On the other hand, it probably does raise arterial pressure to a slight extent. If the hemorrhage is so profuse as to produce collapse, it may be advisable to administer small doses of aconite frequently, until the arterial tension is lowered considerably, or to supplement it by frequent small doses of chloral, which will quiet the circulation, allay cough, and tend to produce sleep. The application of a small ice-bag over the part of the lung which is believed to be in difficulty has been recommended by many physicians, and by reflex influence may do good, if the blood is coming from the bronchial vessel which is supplied with nerves and muscular fibers; on the other hand, if the hemorrhage is from one of the pulmonary vessels it is hard to imagine how it can exert any influence, since these vessels are practically devoid of both nerves and muscular fibers. Curiously enough, Daremberg and Yeo have both asserted that the application of a small ice-bag to the perineum is efficacious in controlling pulmonary hemorrhage, probably by altering the circulation in the chest.

Our attention has been called to this matter once more by an article read before the Section of Medicine of the College of Physicians at Philadelphia by Dr. F. A. Packard, in which he took the attitude that ergot was inadmissible in most of these cases, and also by a paper read before the last meeting of the Association of American Physicians by McPhedran, of Toronto, in which, to use his own words, he "dealt with the fallacy of much that is popular in the treatment of this usually alarming condition, rather than afforded anything new in the manner of its treatment."

Finally, in conclusion, it is well to remember the notes which have been made in the Therapeutic Gazette concerning the value of calcium chloride, given for the purpose of increasing the coagulability of the blood, and also those which have been made about the value of gelatin given subcutaneously for this purpose; nor should we forget the great value of subcutaneous or intravenous injections of normal salt solutions prepared according to the formula of Dr. Locke, of Harvard, and now on the market put up in concentrated sterile solutions amounting to one ounce each, which when added to a quart of pure water produce at once the artificial blood-serum.

Recognition and Treatment of Infantile Scorbutus.

Thanks to the efforts of a number of American physicians, the fact has now become well recognized that scurvy is by no means an unknown condition in young children, and careful medical men are continually meeting with instances in which the disease appears, to the great surprise of careless physicians and to the parents, the latter being in most instances well to do and providing their children with expensive artificial foods.

That the condition is one which often is not diagnosed correctly is proved by the fact that these children often continue on the same diet for a long time after they are known to be ailing, and perhaps there is some excuse for the failure to make a correct diagnosis when the symptoms are somewhat aberrant. On the other hand, we not infrequently see cases in which the disease is so manifestly present that it is hard to understand how it could be overlooked, and we have recently seen several cases which have impressed this fact upon us.

In the Journal des Praticiens of November 26, 1898, Comby reports a case of this character in an infant of thirteen months who
was supposed to be suffering from acute articular rheumatism, as there was swelling of the lower extremities and painful pseudoparalysis. The child was pallid, lacking in appetite, and exceedingly feeble; the gums were reddened and tumeied and bled easily. The milk that the child had received had been sterilized at high temperature. Because the child was thought to be suffering from rheumatism it had been receiving salicylate of sodium, but this was immediately replaced by the administration of proper quantities of milk, orange juice, and a puree made of potato. Within eight days the condition of the child was greatly ameliorated; the hemorrhagic gums and the pain in the limbs had disappeared; there was a marked diminution in the periosteal hematoma on the femurs; and eight days later Comby considered that the patient was absolutely cured.

In one of the cases which we have recently seen a dentist had been called again and again to lance the gums because they were so swollen that they continually covered the teeth as rapidly as the teeth were cut. There was marked loss of power in the lower extremities, a condition of laryngeal spasm, and general cachexia.

In another case there had been repeated attacks of violent laryngeal spasm, and the child was said to have cried continually night and day for two weeks, nothing quieting it, and all efforts to quiet it by walking with it or rocking it simply seemed to increase the loudness of the cries, which was natural, considering that there was present that peculiar tenderness of the joints and vertebrae which is so common in this affection. In both of these cases the proper regulation of the diet and the use of small doses of phosphate of sodium to regulate the bowels and to provide bone salts, and the use of proper broths in which bones had been boiled, resulted in remarkably speedy recovery of the infant.

---

**THE ABUSE OF QUININE.**

We have at various times in the editorial pages of the Therapeutic Gazette, and in several original articles, called attention to what we consider the modern abuse of the drug quinine, for at the present time it is a remedy which is used in almost as many conditions and in as excessive doses as was iron some few years ago. Not only do we believe that certain conditions may exist in the course of malarial disease in which quinine is not only useless but harmful, as we have pointed out recently in an article in the Medical Record of January 7, but also that it is used in excess in many other conditions which are in no way associated with malarial infection particularly for the purpose of breaking up acute inflammations due to exposure to cold and in the treatment of influenza.

Our attention has once more been called to this question by a letter sent by Dr. Dolloff, of Beverly, Mass., to the Philadelphia Medical Journal, in which he speaks of what he calls the "quinine fad" which has taken hold of the profession, and then proceeds to point out that in his opinion the drug is frequently abused, and to state that he thinks that some of the circulatory depression and nervous symptoms manifested by patients who are suffering from influenza or convalescing from this disease are in reality due more to the quinine than to the infection. Our own view is that he is quite correct in this theory. While it is true that small doses—two or three grains two or three times a day—exercise an important influence upon the general system and apparently increase nervous tone, it is nevertheless a fact that larger doses, such as ten or twenty grains three times a day, go further than this, and like most drugs when given in excess produce depression and decrease vitality. Twenty grains of quinine in the average individual exercises a distinct depressing influence upon the circulatory system, and aside from its harmful influence upon the gastrointestinal tract, we believe that these doses also exert some effect upon the blood and nervous system.

When the day arrives in which the profession recognizes that a drug which is a specific in some conditions is not of value in all, much benefit will be the property of our patients, and the routine use of quinine in almost every ailment with which we come in contact is without doubt as bad therapeutics as its fearless administration is good therapeutics in the presence of the active malarial parasite.

---

**THE TREATMENT OF VESICAL OBSTRUCTION INCIDENT TO ENLARGED PROSTATE BY GALVANOCAUTER Y INCISIONS.**

It was about twenty-five years ago that Bottini proposed to overcome the obstruction due to a urethral or vesical enlargement of the prostate by forming an artificial channel through the obstructing mass by means of a knife heated to the cauterant point by elec-
tricity. This method was received with scant favor, since it required for its execution an expensive and complicated instrument, and in the preantisepctic period of genito-urinary surgery was apparently attended by grave dangers of sepsis and hemorrhage. The majority of writers of that day, and up to within a very recent period, have either neglected to mention this operation, which is known as Bottini's, or have condemned it without qualification. It was probably the communication of Freudenberg which attracted general attention to the possibilities of good inherent in a division of the obstructing part of the prostate by the galvanocautery knife.

Within the last year numerous contributions from different authors have appeared on this subject, and though it is customary for the first reports as to the success of a new operation or a revived old one to be optimistic and hence unreliable, there seems good reason to believe that the modified method now practiced is a valuable addition to the list of operations applicable to the prostate, and is one which from its simplicity, its apparent low mortality, the comparative ease of its performance, and the absence of external cutting or disfigurement of any kind, is likely to save many lives, since patients will submit to this means of treatment at an early stage of bladder involvement before irremediable changes have occurred.

Some reasons for the favor with which Bottini's modified operation is now received are:

1. The efficiency and comparatively moderate cost of the appliance.
2. The lessened danger of infection because of a more thorough knowledge of urethral antisepsics.
3. The modification of the operation in such wise that in place of forming an artificial groove or tunnel, deep cautery cuts are made in various directions, causing the prostate to shrink and thus enlarging the natural opening.

Abstracts, giving in detail the results of this operation, will be found in the present number of the Gazette. Meyer's article is particularly important, since he is an accurate observer, ranks with the first genito-urinary surgeons, is thoroughly skilled in operative technique, and is particularly fitted to deduce just conclusions as to the value of a method. He states that a tabulation of 164 cases shows that 80 were cured, 44 were improved, 26 were not improved, and 14 died. Meyer holds that the risk of this operation is less in small, comparatively avascular prostates associated with normal bladders and upper urinary tracts. As a result of his operations he is ready to advise every patient with uncomplicated prostatic enlargement to submit to the galvanocautery treatment as soon as resort to continued self-catheterization has become imperative.

EXTENSION IN THE TREATMENT OF FRACTURES OF THE LOWER EXTREMITY.

It is a commonly accepted belief in the profession that simple fractures of the shaft of either the femur or the tibia and fibula are comparatively trifling injuries, which are attended at most by a confinement of from five to eight weeks in bed, followed by a similar interval of slight disability, and that union takes place with a shortening rarely greater than three-quarters of an inch—often much less than this. It is probable that the great majority of fractured femurs are treated by Buck's extension or some modification of it—i.e., weights secured to the limb by plaster supplemented by splints—while fractures below the knee are very commonly treated in the fracture box and without extension.

The vast majority of fracture cases are those which apply to hospitals for treatment; hence the subsequent course cannot be followed. A very brief study of old fractures of the lower extremity will, however, convince whoever takes the trouble to make such an investigation that disability following fracture of the femur commonly lasts six months and often persists for a year, and is occasionally lifelong; that fractures below the knee cripple for at least one-half this time; and that the shortening in cases of femoral fracture is rarely less than one inch, and frequently varies between one and one-half and two and one-half inches.

It is because of such unsatisfactory results that many surgeons have supplemented the extension treatment by the application of the plaster-of-Paris bandage during complete anesthesia, while the fracture is thoroughly reduced by traction and manipulation. This method is open to the objection that the seat of fracture cannot be subject to repeated examination, and that hence deformity can take place beneath the plaster dressing when the latter becomes loose from the atrophy, which always follows severe bone traumatism.
A contribution of Bardenheuer (Centralblatt für Chirurgie, November, 1898) is of interest in this relation, since it points out that the shortening is often due to the use of too little extension. Usually eight to ten pounds is employed in fractures of the femur. Bardenheuer used from fifteen to thirty pounds, always running his plaster strips above the seat of fracture—as high as the trochanter when the femur is broken; to the middle third of the thigh for fractures below the knee. He states that his results were admirable, and that of 2000 cases treated there was not one instance of non-union.

This suggestion as to the added amount of traction which can be borne with safety is an important one; supplemented by examination with the fluoroscope, and by repeated careful measurements, it should enable the surgeon to obtain much better functional results than have heretofore been the rule. The increased length of the extension strips, and the selection of a stout resin plaster (probably the best is that known as doeskin), will enable a much greater amount of traction to be employed than if the rubber plaster is used. The latter nearly always irritates the skin, often to such an extent that it has to be removed.

Reports on Therapeutic Progress

THE INFLUENCE OF DRUGS UPON GASTRIC CHEMICAL PROCESSES.

Under this heading we have to discuss three main points, we are told by Herschell in the British Medical Journal of October 29, 1898:

1. The action of drugs in diminishing the secretion of hydrochloric acid.

2. In promoting the secretion of gastric juice.

3. In arresting fermentation in the stomach.

Since the discovery of hyperchlorhydria it has been one of the most difficult problems to find some drug which would diminish secretion of hydrochloric acid in the stomach. In some cases, which we now know depend upon absolute increase in the amount of secreting glandular tissue, this must be obviously impossible, and we must rely upon a bland unirritating diet. In the neurotic group of cases, however, it should be theoretically possible to effect something, and one naturally thinks of belladonna. This drug, and its alkaloid atropine, have been extensively tried by many workers in this field of medicine, but with very varying results. Herschell has notes of several cases of his own in which they appeared to diminish the acidity of the stomach contents, but with the drawback that the unpleasant specific effects of atropine were experienced by the patient. He has also tried chloral and morphia without success. Latterly he has been administering preparations of tannin with hopeful results, and quite recently good results are being obtained by lavage of the stomach. The lavage is carried out with a solution of carbonate of sodium, then with a one-per-cent suspension of magnesia usta, and finally with a half-per-cent solution of tannin. Hemmeter, who has made an extensive trial of this method, uses sometimes, instead of the tannin, a suspension of bismuth subnitrate.

In the opposite conditions of hypochlorhydrism and achylia we have to try and increase the amount of hydrochloric acid secreted by the stomach walls, and curiously enough, the agent which appears to give the best result is this acid itself, and it may be safely given in far larger doses than are usually prescribed. When one bears in mind that the quantity of acid contained in the gastric juice during the height of the digestion is 0.2 per cent, it will be apparent that a drachm or so of the dilute acid administered by the mouth will be quite harmless. Herschell points out that the absence of free acid in the stomach contents does not invariably prove that the hydrochloric acid is in defect. The free acid which is present in the stomach is merely the surplus remaining after all the albuminoid articles of diet have satisfied themselves, and it is quite possible, where the demand and supply are pretty evenly balanced, for digestion to be proceeding tolerably well in the stomach without there being any free acid discoverable by Congo red or other tests. One is therefore not justified in diagnosing absence of hydrochloric acid unless the combined acids have also been estimated. This can be easily done by subtracting the acidity found by alizarin from that demonstrated by phenolphthallin. The former is the total acidity with the exception of the combined acid, and the latter the total acidity. The amount of free hydrochloric acid is easily estimated by dymethyl-amido-azo-benzol.

The other agents which appear to have a distinct action upon the secretion of gastric juice are strychnine, the vegetable bitters, and the salts of orexin, but it is impossible to say at present how much of their effects is due to their local action on the mucous membrane of the stomach, and how much to a
stimulation of a hypothetical hunger center in the medulla.

The old idea that the secretion of acid gastric juice could be increased by the administration of an alkali before a meal, we may take as an exploded superstition.

Of course, in cases where the defect of the gastric secretion is due to an inflammatory disease of the stomach, we must cure this before we can hope to restore it; and we shall probably meet with a measure of success unless the gastritis is of so long standing that the majority of the gastric glands have undergone obliteration.

The search for an antiseptic agent which will prevent abnormal fermentations in the stomach is futile, as in most cases we can produce better results by removing the conditions which render it possible.

The germicide provided by Nature is the hydrochloric acid of the gastric juice, and although it will not destroy all bacteria in the stomach it will sufficiently inhibit their action to allow the digestive processes to proceed in a normal manner.

A further safeguard against fermentation in the stomach is the fact that bacteria require a certain time in which to act, and that before this has arrived the stomach usually empties itself into the duodenum. The causes, then, of gastric fermentation are: (1) deficiency of hydrochloric acid; (2) defect in the motor power or peristalsis of the stomach.

The rule of practice which Herschell adopts is: Whenever by the exhibition of hydrochloric acid and regulation of the diet he is unable to control abnormal fermentation in the stomach, he washes it out sufficiently often to keep the patient in comfort. He is convinced that we cannot administer sufficient quantities of any known antiseptic to render the stomach sterile without injury to the patient.

THE TREATMENT OF DYSEPSIA.

Calwell, in the British Medical Journal of October 29, 1858, tells us that he thinks that there are a few clinical points in regard to the treatment of two forms of dyspepsia that, although mentioned, are not sufficiently insisted on. First, as regards rest in the dyspepsia of the overworked. As physician to a large nurses' home and training school with about one hundred inmates he had had particularly good opportunities of observing this phenomenon. A form of painful dyspepsia, due to the usual combination of gastric insufficiency and gastric irritation, was fairly common. Formerly he treated this with change of diet—the cooked milk diet and some gastric sedatives and alkalies—but he allowed the patient to continue duty. The results were unsatisfactory.

The pathology of such cases is simple, although far-reaching. A person is overworked; there is more or less nervous exhaustion; and owing to the habit of eating too quickly, to the prevalence of bad teeth, to the rushing back to work without the requisite rest, and to the rather frequent exhibition of the great digestion delay, tea, the stomach generally feels this exhaustion earliest. If this be the correct pathology the treatment is clear. We must give general rest for the whole system, allowing an accumulation of nervous energy in particular, but also in the various organs of the body, and at the same time local rest for the stomach. Owing to the means at his disposal and the careful watch that could be kept over the patients, Calwell was able to follow the effect of absolute rest with general treatment with a precision one could not secure in private practice or among the out-patients in hospital; such cases refuse to go to bed or to come into hospital.

The treatment can be summed up in a few sentences. Absolute rest of body and mind in bed for from two to ten days; a carefully regulated diet, beginning with a small tea-cupful of cooked diluted milk every two hours, gradually increasing to a fairly full diet; and, lastly, some mild alkaline sedative before food. The above form of dyspepsia is exceedingly common both in private practice and amongst the out-patients of our hospitals. His desire is to emphasize the necessity of absolute rest, thus treating the incipient state of bankruptcy of the general strength, more especially of the nervous system. The results are convincing.

Calwell next speaks of the second form of dyspepsia. Suppose such a condition as the above is allowed to linger on; suppose one is content to prescribe medicines and modify diets, but without a cure, as not infrequently happens. The condition becomes one of irritation due to organic acids, fermentation, with, as before, insufficiency. In very advanced and chronic forms, where the affection has gone so far as to lead to dilatation from weakening of the coats of the organ, lavage is the remedy that appeals to our ideas of the pathology. But what about the milder forms—the intermediate stages where a diagnosis of dilatation, of chronic ulcer, of chronic catarrh, is made by each succeeding
medical man in turn, as he is consulted? The treatment of such a condition in the early stages is as follows: Rest is important, but the absolute rest demanded in the former instance is not so here; on the other hand, it must be of much longer duration and carried out under the hygienic conditions of rest in the open air, at the seaside or in the country, not in bed. Secondly, carefully regulated diet under the usual principles. And lastly, modified lavage, as follows: Thrice daily from one to two hours after meals, according to the onset of the pain, swelling, and general uneasy symptoms, a warm alkaline draught; this neutralizes the organic acids, it stimulates the stomach to contract, and as it dilutes the contents they are passed with greater ease into the intestine; we endeavor to stop further work on the part of the stomach as regards that meal, and so give it rest: and we send the food where it should go, into the intestine to complete its digestion. It is a mistake to try and force the weakened stomach to go on digesting with pepsin: give it rest, as you would a joint still swollen, painful, and stiff from inflammation. The form of warm alkaline draught employed is one of bismuth, soda, and heavy magnesia.

The two points Calwell urges in connection with many forms of dyspepsia are: (1) The necessity of absolute bodily and mental rest; (2) the necessity of not trying to force the stomach to continue digestion when it is repeatedly telling us that it cannot, but to devise means of removing the contents after a certain period without actually passing the tube.

In discussing this subject Eccles said in regard to megastria it certainly seemed that the less serious form of ectasia, due to atony and atrophy not going on to degeneration of the mucous membrane, nor ending in general fibrosis, was greatly on the increase, or at any rate he had seen a greater number of cases in the last three years than in the same length of time before. He did not propose to burden them with statistics which were not sufficiently large to establish facts.

In over 500 cases with marked dyspeptic symptoms occurring in the past ten years in his practice there had been 128 cases of dilatation of the stomach, of which forty-two had been treated in the last three years. The majority of cases were spoken of as "chronic dyspepsia" or "atonic dyspepsia;" and alkalies, acids, bitters, tonics of all kinds, and the inevitable changes of air had been often prescribed with the want of success such proceed-ings usually entail. He thought that the sufferers from this comparatively mild form of stomach enlargement drifted on without improvement as a rule for months, or even for years, until their symptoms, becoming somewhat conspicuous, attracted attention, when sometimes success followed appropriate treatment.

Examination of the stomach contents after a test breakfast revealed deficiency of free hydrochloric acid, and the salol test was greatly delayed. Still some power of contraction continued to exist, and the patient appeared to suffer rather from general disturbance of nutrition than from the more severe local effects of true megastria when associated with malignant or non-malignant pyloric obstruction, fibroid degeneration, or adhesions. It is a great pity that so many sufferers from chronic or repeated attacks of gastritis drift from bad to worse, until wide-spread destruction of the mucous coat leaves little hope of recovery by any means. When, however, atony has not developed into atrophy, the disease can be arrested by a plan of treatment which is preeminently rational and successful. The patients should be rested in bed, fed at first on pulped proteid foods and milk; the abdominal walls should be manipulated three or four times in the twenty-four hours; and the contents of the stomach should if possible be mechanically expelled into the duodenum three-quarters of an hour after the principal meals of the day. The patients should be encouraged to assume a tilted-up position, with the buttocks on a higher level than the shoulders, as often as they can do so without undue fatigue.

In more than 100 cases this method, employed for periods varying from three to ten weeks, had proved successful in decreasing the size of the stomach, greatly improving the powers of assimilation, and increasing bodily weight and bulk. In this atonic dilatation of the stomach Eccles had frequently been able to add an average of five pounds a week to the weight of the patient under his care without the use of the stomach-tube, save only in the first few days to prepare the organ for more rapid absorption and evacuation of its contents. A similar plan of treatment had also been adopted in some forty cases of gastrop'tosis, of which twenty-seven uncomplicated by other forms of enteroptosis were published in the West London Medical Journal for July.

For conditions of true ectasia ventriculi
complicated by destructive processes of the stomach wall and obstruction of a character irremovable save by surgical means, it is worth while to see how improvement can be obtained by lavage, massage, dieting, and rest before surgical procedures are initiated, for at any rate unless the patient is in a very parlous state he might be rendered more fit to sustain the shock of abdominal section, even when gastroenterostomy apparently affords the only prospect of relief.

THE LOCAL USE OF THE AQUEOUS EXTRACT OF SUPRARENAL GLANDS OF THE SHEEP IN THE NOSE AND THROAT.

In the New York Medical Journal of December 24, 1898, Swain concludes a paper with the following words:

1. We have in the aqueous extract of suprarenal-glands a powerful local vasoconstrictor agent and a contractor of erectile tissue, which it is safe to use in very considerable amounts without any dangerous or deleterious effects locally, or to the general constitution of the individual.

2. These local effects can be reproduced in the same individual apparently any number of times without entailing any vicious habit either to the tissue or to the individual.

3. The use of the extract seems to rather heighten the effects which may be expected from any given drug which may be locally used after it.

4. In acute congestions it has its widest application and greatest opportunity for good; but also in certain chronic conditions of hay-fever type, where edematous tissue seems prone to develop, it can be relied upon as one of the most helpful adjuvants which we have at command. The only difficulty seems to be in producing it in quantities and in preventing decomposition on standing, which objection will be probably easily overcome by laboratory experiments.

THE USE OF MORPHINE IN HEART DISEASE.

The Boston Medical and Surgical Journal of December 22, 1898, contains an interesting editorial on this topic, in the course of which it expresses the belief that opium still remains one of those drugs whose varied uses must be learned empirically from clinical observation rather than from any theoretical consideration of its modus operandi, or from any study of its physiological and toxicological effects in healthy men and animals. Its wide range of action, according to the dose and form of administration, makes it applicable to certain cardiac affections, especially such as are attended with dyspnea and pain. In many cases of angina pectoris, despite the undeniable advantages to be derived from nitroglycerin and nitrite of amyl, it must be the main reliance. By the consent of the profession, morphine is the preparation most generally chosen, and the popular opinion that it is both a respiratory and cardiac stimulant (helping the heart perhaps by a general vasodilator action, besides allaying morbid irritation and pain) is not without foundation.

Is morphine equally beneficial in aortic and mitral disease?

Some, as Dujardin-Beaumetz, think that it is of especial benefit in aortic regurgitant disease. Here it is, he says, a sovereign remedy—as much so as digitalis in mitral insufficiency—opposing the two great symptoms which result from lesions of the sigmoid valves, the cerebral anemia and the dyspnea; it also combats the neuralgias of the cardiac and pulmonaryplexuses. T. Clifford Allbutt finds morphine equally serviceable in mitral regurgitation, one hypodermic injection being given in the evening. Bartholow also speaks favorably of morphine injections in mitral disease. Germain Sée extols these injections in cardiac dyspnea, but calls attention to the evils attendant on the use of morphine, such as disturbance of the appetite, digestion, and nutrition, formation of the morphine habit, diminution of the urine, etc. He has seen morphine bring on the Cheyne-Stokes respiration when injudiciously administered.

Osler thinks that the calming influence of opium in all conditions of cardiac insufficiency is not sufficiently recognized.

Tyson takes the ground that persistent cardiac dyspnea, dependent so often upon passive congestions and pleural effusions, not otherwise relieved, demands an opiate, of which morphine is the best. In milder conditions Hoffman's anodyne may be tried.

The American translation of Strumpell speaks of morphine in cardiac disease thus: "The dyspnea of heart disease is usually the most distressing symptom of all. Here, too, our chief task is, of course, to restore the compensation; but failing this we must try to relieve the dyspnea symptomatically. Morphine is most efficient in this respect. In general morphine is, next to digitalis, the most indispensable remedy in the treatment
of severe heart disease. It is usually well borne and procures great relief, especially if given subcutaneously. If we have to do with the last stage of the disease we need not spare large doses."

Dr. F. S. Toogood, in the London *Lancet* of November 26, 1898, regards the notion that morphine is dangerous in heart disease attended with renal insufficiency as a prevalent one; he disputes its justness, and commends the use of morphine in desperate cases where other remedies have failed. Although doubting the prevalence of such a view among our best practitioners here, the report of experiences which were illuminating to him may not be amiss for others, as we are inclined to agree with Osler, that the "calming influence of opium in all conditions of cardiac insufficiency is not sufficiently recognized."

Toogood has employed morphine hypodermically in those distressing cases (mainly of mitral incompetence) where the exhibition of digitalis, strophantus, and convallaria excites vomiting, where the stomach retains practically nothing, where the heart is extremely irritable and irregular in rhythm and the pulse in volume, where often an ever-present dyspnea renders the condition of the patient intolerable from exhaustion and want of sleep, and where there may be also edema from failing circulation, and a scanty amount of albuminous urine. In these cases the subcutaneous injections have given most gratifying results. The pulse has become steady, strong, and regular, the edema has disappeared, the dyspnea has been relieved, and the urine, instead of being scanty, high-colored, of high specific gravity, and containing albumen, has become normal in amount and character, and the albumen has become much less or has entirely disappeared. Dr. Toogood reports five cases, two of them typical cases of angina pectoris, where life was apparently prolonged and a fair measure of comfort maintained by morphine injections; no bad effects from the remedy were noted. One of the other patients had mitral regurgitation with edema and dyspnea, urine scanty, loaded with lithates and somewhat albuminous, pulse small, rapid, and irregular. Under the influence of morphine injections he was able to sleep quietly and comfortably; the pulse came down to 80 beats per minute; the urine increased to seventy ounces; the edema disappeared; and the albumen cleared up. His general health so far improved that he was able to resume most of his former occupations.

Another patient had both aortic and mitral regurgitant disease, and all the ordinary cardiac stimulants having failed, resort was had to morphine hypodermically. A fresh lease of life was given this patient. In another case diagnosticated as obstructive mitral disease, the pulse, first tumultuous and rapid, became almost imperceptible, and the patient was in a state of collapse. The urinary secretion was nearly suppressed. Under the influence of a hypodermic injection of one-fourth of a grain of morphine every twelve hours the patient began to improve, and was able to sleep; the vomiting, before persistent, ceased; the urine became normal in amount; and the tumultuous action of the heart subsided. This patient ultimately recovered so as to be able to resume work.

Dr. Toogood closes with the remark "that morphine in large doses is a cardiovascular depressant is well known, but its soothing effects upon irritable conditions of other organs are so well recognized that I am inclined to think that the undoubtedly beneficial results in cardiac disease are due to its action upon the nervous apparatus of the cardiovascular system, both central and local, bringing rest to an overstrained organ, and allowing it the chance of developing its recuperative power."

---

**A STUDY OF SIXTY CASES OF LOBAR PNEUMONIA.**

The *Medical News* of December 24, 1898, contains an article on this topic by A. A. Smith. He details the plan of treatment as follows:

All of the patients were given water to drink—indeed, they were urged to take water very freely. During the acute stage the diet consisted chiefly of milk, broths, soups, jelly, and eggs, when the patient was able to take them. Kumiss and matzoon were also allowed. When pain was a marked feature during the first days of illness morphine was used sufficiently to relieve it. In some cases in which pleurisy was a complication and the pain severe, adhesive plaster strips were applied to the side to restrict movement. As most of the patients were alcoholic and delirium was a prominent feature, with wakefulness, hypnotics were used, but always with care, the choice of these depending somewhat upon the amount of delirium. In some of the cases twenty to thirty grains of chloral amid at night gave satisfactory results. In others a combination of bromide with mod-
erate doses of morphine seemed to work more satisfactorily. Sulphonal and trional were also employed in the early stages in some cases, and apparently produced no depressing effect; on the contrary, refreshing sleep resulted. Alcohol in the shape of whiskey was used in a large proportion of cases, but more especially because the patients were alcoholic and on account of its sedative effect rather than as a cardiac stimulant. The quantity of whiskey varied from four to eight ounces in twenty-four hours, but in a few cases this quantity was increased to ten or twelve ounces.

Cathartics were used as indicated, and as a routine practice in cases which were seen early in the development of the disease.

Of the coal-tar preparations, a combination of phenacetin and caffeine was employed in some of the cases seen early in which there was severe headache, dry skin, high temperature, severe muscular pain, and marked restlessness. This was given in small doses—phenacetin five grains and caffeine one grain—and repeated every three, four, or five hours, the indication being the moderate reduction of temperature, if along with this reduction the unpleasant symptoms mentioned were decidedly relieved. This combination was not used in any instance after the third day. Digitalis was used: only in cases in which there was valvular cardiac disease with predominant dilatation, and because of this condition of the heart.

Strychnine and glonoin were used in a large proportion of the cases as a routine and from the beginning of the treatment. Strychnine was given in doses of from one-fiftieth to one-thirtieth of a grain every three or four hours, according to the severity of the case and the effect produced. Glonoin was given every two hours in the daytime and every three hours at night, in doses of one-fiftieth of a grain.

Baths in the form of the bed-bath or sponge-bath were given in cases in which there was high temperature (above 103° F.) and marked restlessness. No plunge-baths were given. These baths were not given at regular intervals, but according to indications—i.e., temperature of 103° F. and over with marked restlessness. The temperature of the baths ranged from 75° to 65° F. In ten cases compresses were applied to the thorax at a temperature ranging from 75° to 65° F., the indication being the same as for the giving of the bed-bath or sponge-bath. No special pains were taken in the fitting of the compresses. A sheet doubled four times was dipped in water at the temperature named, and was then wrapped around the patient from the axillary region down to the hips. The temperature of the water varied with the temperature of the patient. The compress was applied to the thorax because this was the most convenient region, and not because it was believed that it would produce any special effect upon the process going on in the lungs, but rather for its effect as an external application of cold. It was noticeable that in the cases in which the compress was applied there was at first objection on the part of the patient, but within twenty-four hours it would be asked for and welcomed. The compresses seemed to reduce the temperature, diminish the frequency and increase the force of the pulse, quiet the nervous system, and produce refreshing sleep. Almost invariably the patient said that he was more comfortable after the compresses had been resorted to.

In two instances, as a matter of experiment, these compresses were applied around the body from the lower part of the thorax down to the thighs, over an area corresponding in size to the thoracic region, with the result that they had the same effect as when applied over the thorax. It is simply a modification of the bath and seemed to act by stimulating the respiratory and circulatory centers, reducing temperature and quieting nerve perturbation.

In cases in which pulmonary edema developed, or in which cyanosis was a marked feature, inhalations of oxygen gave great relief. This was administered freely for from six to eight minutes at a time at intervals of from half an hour to two hours, depending upon the severity and persistence of these two symptoms.

MYXEDEMA AND ALLIED DISORDERS.

Ord writes upon this topic once more in the British Medical Journal of November 12, 1898. He tells us that under the head of treatment it must first be observed that until the introduction by Dr. Murray of the practice of making hypodermic injection of a glycerin extract of the thyroid gland, no remedies could be spoken of as effective. Arsenic and iron were suggested by the very obvious presence of anemia; and each in its way often produced some improvement in the general health of the patients. The hypophosphites were used where the nervous weakness was particularly evident, and jaborandi or the
salts of pilocarpine were used in order to favor the occurrence of perspiration. In addition to the use of drugs, the introduction of portions of the thyroid gland into the tissues of the body has been used by several observers. Some found a resting-place for the gland in the peritoneal cavity, others in the tissues beneath the skin. The writer has made use of the latter method in several cases, choosing a spot over the upper part of the pectoralis major muscle, where the portion of the thyroid gland could be deeply embedded in subcutaneous tissue.

In all cases some improvement rapidly followed the operation; the skin began to get moist, the patient's face to fine down, and the hair recovered somewhat its healthy character; but in no very long time it could be ascertained by the touch that the embedded gland was diminishing in size, and at length it disappeared. With its disappearance passed away all the signs of improvement. It is just possible that by regular repetition of the process something like cure might have been effected, but Ord does not know that any one has performed the operation more than once or twice, the difficulties of such a proceeding being very obvious. It must be stated that the embedded glandular structure was taken from a goitre just removed by operation.

After Dr. Murray had made his important discovery, Dr. Hector Mackenzie found that the internal administration of the gland or its preparations brought about as marked an improvement and progress to cure as had been effected by the hypodermic injections, and the internal administration of the thyroid gland in one way or another is the method of treatment now usually adopted. It appears that the administration of the thyroid gland itself, when it can be carefully and regularly maintained, is the most appropriate form of treatment. The gland may be finely minced and administered raw with sugar or salt, or may be lightly cooked. The size of the gland—mainly obtained from the sheep—varies a good deal, and such variation is to some extent a justification of the administration of an extract obtained from a number of glands so as to get something like an average. In one case still under occasional notice an affectionate husband has been at the trouble to procure regularly thyroid glands from sheep and to prepare them in a raw state for administration to his wife. The original quantity administered was one gland a week. As the patient has improved, the frequency of administration has been diminished, but it still goes on as it has gone on for some years, and at the present moment the lady presents no signs whatever of the disease.

It is possible to give the thyroid gland too frequently. When the knowledge of its efficacy as administered internally first became known the writer gave to a patient, who was so ill as hardly to present any chance of maintaining life, one gland a day for four days in succession. At the end of that time she suffered from violent headache, vomiting, and pains in the limbs, with rise of temperature amounting to 60° F. With such a lesson the gland was administered at longer intervals—namely, of a week to ten days—with ultimately the greatest benefit. But to procure fresh and healthy glands and to prepare them in the proper way involves a great deal of trouble, and its use may be replaced by the administration of Dr. Murray's glycerin extract in doses varying from ten to thirty drops a day, or every second or third day, according to the effects produced and to the patient's power of bearing the influence of what we may now call the drug. Still more convenient and not ineffective are the preparations in the form of tabloids now in common use. Some of these contain the dried and crushed gland, others extracts of it, such as the excellent powders devised by Mr. Edmund White, the therapeutist of St. Thomas's Hospital. On the whole, Ord prefers the extracts of the whole gland to any kind of principle derived from it by chemical processes. Perhaps the next best form is the dried and powdered gland of the Pharmacopia.

A good deal of extremely interesting work relating to the preparation has been done by various observers, and Ord draws attention to "Observations on the Chemistry and Action of the Thyroid Gland," by Dr. Hutchison, demonstrator in physiology, London Hospital Medical College.

According to Dr. Hutchison and others, colloid matter prepared in various ways from thyroid gland is found to contain a definite quantity of iodine, which appears to be present in the form of what has been called "iodothyrin" (Bergmann).

We may note in passing that, according to Dr. Hutchison, parathyroids when administered in myxedema have no effect upon the disease, although in operations on dogs no myxedema occurs if the parathyroids are not removed as well as the thyroid.
CONSTITUTION AND ITS MODERN TREATMENT.

We have already quoted a paper by HERSCHELL on this topic. In another paper in the Clinical Journal of November 16, 1898, he proceeds to tell us that the very first thing to do when commencing the treatment of a case of constipation is to make absolutely certain that there is no fecal matter abnormally retained. In some cases we will have ascertained its presence by methods of examination; in others there will be symptoms present which warrant us in suspecting it; but in others both of these will be absent. In the first two instances one can certainly feel no hesitation in washing out the bowels, but in the last the question arises whether we may assume that the bowels contain nothing abnormal, or whether we should make sure by one or two large enemata. In the writer's opinion we should certainly assume that there may possibly be fecal retention, and act accordingly, for the following reasons:

It is extremely unlikely that habitual constipation can have existed for any considerable length of time without some fecal masses being abnormally retained; many fecal masses cannot be discovered on a physical examination of the abdomen; chronic fecal retention does not invariably give rise to symptoms of any kind; we certainly cannot cure the constipation as long as there are any fecal masses permanently retained in the intestine, and the treatment for their removal can do no possible harm to the patient. We will therefore commence our treatment by making certain that the large intestine is empty, and thus have a fair start in the management of the case, with the definite knowledge that we have eliminated a possible factor.

One or more of the following four conditions may be present, therefore our measures will vary accordingly:

Fecal masses may be felt by an examination per anum blocking the rectum.

Masses may be made out by palpation in the sigmoid flexure.

Masses may be felt in the remainder of the colon or in the caecum.

There may be no physical evidence at all of anything abnormally retained.

Any one or more of the first three conditions may be present in conjunction. The author takes them in order, and points out the treatment to be pursued in each case. The rectum must be emptied before we can do anything more in the treatment, as obviously until this has been done no fluid can be introduced into the upper parts of the colon. In many cases a simple enema of hot soap and water will be all that is required, but in others it proves of no avail, and it is necessary to use some agent which has a solvent action. Two substances are of especial value for this purpose—olive oil and ox-gall. Olive oil consists mainly of oleic acid, which is a powerful solvent of feces, and ox-gall acts in the same manner, but more energetically. A combination of the two forms one of the most efficient solvents of fecal matter that it is possible to conceive. The writer states that for a knowledge of this valuable property he is indebted to Mr. William Allingham, who communicated it to him over twenty years ago. It is quite possible that the rectum may be so tightly packed that there may be very little room for any injection to be introduced. Under these circumstances three ounces of the asafetida enema of the B. P., mixed with an ounce of fresh ox-gall or with a drachm of the purified dried preparation, may be used every two hours until an effect is produced. Another method is to introduce a mixture of warm olive oil and ox-gall every night at bedtime, and allow it to remain up all night. In the morning a large enema of hot soap and water will usually empty the rectum.

If, however, the symptoms are urgent, and it is necessary to empty the rectum as soon as possible, continuous irrigation with the double tube is the best course of action, and the writer has designed a special piece of apparatus for this purpose. A large vulcanite tube, long enough to pass beyond the internal sphincter, terminates at the end which is to be introduced into the patient in a large opening with thick rounded edges, and to the other is attached a piece of rubber tube leading into a pail placed upon the floor—or a Kelly's douching sheet may be used. A small orifice is made in the rubber tube about an inch from its junction with the vulcanite rectal one, and through this is passed into the bowel a soft-rubber stomach-tube, with preferably a terminal eye. This in its turn is attached to a douche-can hanging at a convenient distance above the patient. The effect is that the water enters the bowel in a small forcible stream, and the débris leaves it again almost at once by the wider vulcanite one, carrying with it bit by bit the fecal masses which undergo continuous disintegration. It is convenient to introduce the large vulcanite tube before the rubber tube is attached, as this permits the use of an obtura-
tor, and materially facilitates the operation. Such an apparatus may be easily extempo-
rized from any piece of tube of the required
diameter, but one must remember on no ac-
count to use a glass one, as it might possibly
be crushed by spasmodic action of the
sphincter and seriously injure the patient.

When the rectum is empty, or has been
emptied as just described, but masses can be
felt in the sigmoid flexure, enemata of soap
and water, olive oil, and ox-gall are to be
tried as above, but the technique of their ad-
ministration is a little different from that used
when it is only desired to empty the rectum.
Then an ordinary Higginson’s syringe could
be used; now we must make use of a douche-
can raised about a couple of feet above the
patient. If these prove ineffectual to empty
the bowel, continuous irrigation as in the
case of the impacted rectum must be used.
A Türck’s double colon tube is introduced
into the sigmoid flexure, an operation not at
all difficult of execution; one tube is attached
to a douche-can two feet above the patient,
and the other one to a rubber pipe leading to
the receptacle under the bed. The patient
lies on his right side. This irrigation of the
bowel may be kept up for an hour without the
slightest damage to the patient. There
is not the slightest doubt that we owe a
deep debt of gratitude to Professor Türck
for placing within our reach this method of
irrigating continuously the large bowel. By
its aid the treatment of the various inflam-
matory affections of the colon is much sim-
plicated, and we are enabled to remove fecal
accumulations which were hitherto beyond
our aid.

Masses may be felt in the transverse or
ascending colon or caecum.

The large bowel is apparently empty.

Our procedure in both these cases will be
the same. Our object is to completely clear
out any possible retained fecal matters from
the whole of the large bowel. This is accom-
plished by the administration on several days
in succession of a douche of hot water con-
taining a little boric acid or other harmless
disinfectant. Latterly the writer has been
using a normal salt solution. Enemata of
the ordinary size (a pint or two) are useless
for this purpose, as it is tolerably obvious
that to reach, for example, a fecal mass in
the caecum, the whole of the large intestine
must be filled with liquid. Into a normal
adult healthy large bowel half a gallon of
water can be injected without materially
stretching it, and much more is required to
fill the dilated colons which we so frequently
meet with in cases of long-standing consti-
pation.

The problem, then, is to introduce a suffi-
cient quantity of liquid without exciting the
propulsive efforts of the patient. This can
be accomplished by attention to the following
points of detail:

A continuous pressure must be used, not
an intermittent one. One can do this by
means of a douche-can suspended at an
appropriate distance above the patient. With
a Higginson syringe not only will the rhyth-
mic alterations of pressure that are produced
in the bowel infallibly give rise to expulsive
efforts long before a sufficient quantity of
water has been introduced, but one is absolu-
ately unable to regulate the exact pressure
which we are using.

The pressure under which the water passes
into the intestine must be a low one. Any-
thing above two pounds to the square inch
will be dangerous in an adult, much more so
to a child. As the amount of pressure actually
exerted in the bowel depends not only upon
the height of the column of water (i.e., the
distance of the can above the patient), but
also upon the resistance which is met with in
the bowel, it is of great practical assistance
to include a mercurial manometer in the cir-
cuit—that is, if one wishes to do his work
scientifically and intelligently, and to know
exactly what is taking place inside the patient.
By this means one knows the exact moment
when the fluid, ceasing to simply flow into
the intestine, commences to distend it.

The force of gravity must be called in to
assist the passage of the liquid towards the
caecum. The patient must be placed in the
knee-elbow position or on his back, with the
hips raised. Personally, for the latter pur-
pose, the writer uses a special apparatus, but
it can also very well be managed by raising
the foot of the bed on blocks.

It is a distinct advantage to place the flat
of the disengaged hand upon the abdomen of
the patient, as by this means the rapidity with
which the colon is being filled can be esti-
mated.

When the physician has once commenced a
series of flushings of the colon he must on
no account stop them for longer than twenty-
four hours at a time, until the appearance of
the washings informs him that all retained
fecal material has been removed. Otherwise
he may make the patient very ill, as the long-
dried fecal matter being moistened and dis-
solved liberates in the intestines of the patient
the locked-up toxins, and such manifestation as an attack of acute urticaria may supervene. For this reason it is advisable to add to the washing water a little boric acid, orphol, or other harmless disinfectant.

**FURTHER FACTS CONCERNING THE TREATMENT OF THE CHRONIC FORMS OF HEART DISEASE DUE TO RHEUMATISM.**

The London *Lancet* of December 10, 1898, contains an article part of which we have already abstracted for the *Therapeutic Gazette*. In this article Dr. Sansom says that special treatment of the nervous system in rheumatic diseases of the heart, even those which seem to be chronic, is in many cases of very high importance. He says of course he hesitates before concluding that the galvanic current was directly of benefit by influencing the vagus itself. He had, however, observed many cases in which such treatment had given good evidence of success in the treatment of the rapid heart and in the various forms of Graves' disease. Cases in point are detailed in his oration on the Rapid Heart at the Medical Society of London and elsewhere. From observation since of a long series of cases of Graves' disease which have progressed to recovery in a much briefer time than was the case under his former experiences, he cannot doubt that galvanism (the continuous, not the interrupted, current) has a directly favorable effect. He thinks that there is good reason to believe the involvement of the nervous elements, which are the agencies of the cardiac reflexes as well as regulators of the trophic conditions of the heart, is to be regarded as a very important consideration for diagnosis and treatment in rheumatic inflammations and dilatations of the myocardium. He says he is at a loss to explain why one case of pericarditis, of carditis, or of general temporary enlargement of the heart, differs so widely in its symptoms from another without assuming that the involvement of the nerve elements plays an important part in the pathogeny. He has seen, as others have, a case in which the physical signs of pericarditis have been fully manifested, and yet there has been no dyspnea and scarcely any subjective discomfort; while in another case the face denotes anguish, the breathing is rapid and gasping, the suffering is intense, and the signs all show that the patient is at the point of death.

Considering the marked and agonizing dyspnea of some cases of acute pericarditis Dr. D. B. Lees suggested the questions, "Is there a dextrocardiac respiratory center?" and as a consequence, "Is there a dextrocardiac respiratory reflex?" When there is no disease in the lungs and little or no defect in the aeration of the blood, how shall we explain the very obvious dyspnea unless we conclude that there is an involvement of the nervous mechanism? The late Dr. Sturges pointed out in his Lumleian Lectures that in the cases mentioned it might be contended that there was not pericarditis alone but carditis, with the result that the whole substance of the heart was so weakened that the symptoms in question might be explained by the muscle failure. "But," he added, "the extremity of the dyspnea would seem better explained by Dr. Lees' view, viz., that there is an automatic reflex from the right ventricle to the respiratory center, such reflex being called into action by the acute failure of the right ventricle resulting from the inflammatory disease."

Dr. Sansom considers the observations of Dr. Lees and the late Dr. Sturges of very high importance. He says it appears to him proved by a strong array of evidence that dilatation of the heart can occur as the direct result of disease of the nervous system. He has observed it when there have been signs of neuritis of the vagus. In the cases in which the heart becomes dilated in the course of Graves' disease the dilatation is probably due to nerve disturbance. In palpitations of the rapid heart it may be concluded that disorder of the vagus is the immediate cause of the symptoms. In many cases of rheumatic heart disease nervous disturbances of the heart become epiphenomena. So it can scarcely be doubted that a morbid irritation conveyed to the vagus center, whereby the control power and the other endowments of the nerve are weakened, is in many cases a very important contributory factor to produce the ensemble of symptoms. He says, therefore, it seems to him that an attempt to influence the vagus by the continuous galvanic current is a very reasonable procedure; moreover, it is one very easy to accomplish. It is of course best that the method should be put in train by an electrotherapeutic expert, but this is by no means essential. The practitioner in attendance can arrange every detail, and a nurse or the patient can soon be trusted to do all that is necessary, for the regular employment of the method should be continued for many weeks or even months.
Dr. Sansom says he by no means wishes it to be understood that this plan of using the galvanic current for increasing the tone of the pneumogastric nerve is the only plan to be adopted for favorably influencing the nervous system in these cases. Moral agencies—the inspiration of hope, the avoidance of depressing emotions, and the inculcation of cheerfulness—are of high value. And when muscular movements are permitted and tentative training has taken place, changes of scene and climate and the use of baths and systematic exercises are potent agencies for good. He has said elsewhere that allowance must be made for many fallacies when the estimation of the value of treatment by baths and exercises is attempted. He has given in this communication his reason for believing that the enlargements of the heart may occur and recede in a way which may be independent of treatment, and he has cautioned against the danger of pursuing any plan of muscular exercises when rest is of paramount importance. Nevertheless, when all these logical deductions are made, he states he cannot but be convinced that in many cases systematic baths and exercises and the careful following out of a plan of treatment such as that of Dr. Blanc, of Aix-les-Bains, or that of Dr. Schott, of Nauheim, are of great therapeutic value. He feels it only right to state his opinion that there is not infrequently manifested nowadays an influence which works much for evil in disturbing the rational treatment of chronic heart disease. It is the influence of the irresponsible third person—he explains what he means in the form of hypothesis and parable. A patient has experienced an attack of rheumatism with heart involvement, and under the conscientious care of his medical attendant has entered into convalescence. He or she meets the irresponsible third person, who says: “How very ill you are; have you tried the barium and gold treatment?” “No.” “Then your doctor cannot know anything about your case. You must go to my doctor, who knows all about the barium and gold treatment.” Or it may be, “Has your doctor ordered you to Paradis-les-Bains or Weissnicht-wo? Oh! you must go to a doctor who will be sure to order you to go to Paradis-les-Bains or Weissnicht-wo.”

Dr. Sansom says he is sure that these phenomena of interference are not merely visions of the mind, but are distinct dangers to good progress in therapeutics. The lay public are apt to be captivated by fashion in matters medical. They hear of a remedy or a given plan of treatment, and their enthusiasm gets the better of their discretion. Their knowledge is and must be superficial. They reason from the supposed remedy to the disease, not as the conscientious medical man does, from the disease to the remedy. It is the medical man’s duty to keep himself abreast of therapeutic science. He has already in all probability duly estimated the prospective value of the means of treatment suggested by the irresponsible third person. If he has not suggested them it is because he thinks them unsuitable to the given case. To the irresponsible third person every case presenting symptoms of heart disturbance is a case of heart disease to be treated by some blatant method for the cure of heart disease. The intricacies of morbid processes involving the heart are of course unknown to the irresponsible third person. Even in the case of the rheumatic heart, which Dr. Sansom says he has attempted to sketch out, there is much that is intricate and perplexing, and the conditions for treatment are multiform. In other cases in which not only the rheumatic changes but the influences of diseased vessels, of degenerations, of the diseases of maturity and more advanced age are to be considered the conditions are more complex still. A disturbance of the well merited confidence between patient and medical attendant works banefully for the former, and very often the consultant who has thus been patronized by the irresponsible third person feels himself in an undesirable position, for the facts are withheld from him, and the previous history of the patient as offered to him is vague or garbled.

Dr. Sansom concludes by saying that it is the duty of any practitioner who observes a case of rheumatic heart disease, however chronic, to guard his patient against the subtle future dangers of his malady. It is incumbent on him to make himself acquainted with all the therapeutic means which the present state of science indicates. He says he thinks it was Sydenham who said to a lady patient, “Madam, you are entitled to my brains—to all my brains.” The medical man must employ such means as are sanctioned by practical experience according to his own discretion, without being led away by quasi-scientific will-o’-the-wisps. The path is not always easy to find, and light from many sources is to be sought for; but the rule is a good one: “Turn to the right and keep straight on.”
THE TREATMENT OF TYPHOID FEVER.

Dr. Sidney Phillips, of London, writes on this important theme in the *British Medical Journal* of November 12, 1898. After discussing the disease somewhat in detail, he tells us that as regards treatment it will be convenient to speak of heart failure, asthma, and blood failure together. For all of them one essential is to prevent waste of material by diarrhea, or hemorrhage, or profuse sweats, and to supply as much nourishment as can be digested and absorbed.

As regards food, Dr. Barr recommends the giving of solid food whenever the patient "likes it, wishes for it, and enjoys it." He argues that such food will not be likely to cause perforation, as it becomes softened before getting into the intestine, and that perforation only occurs in two or three per cent of cases. The writer thinks cases do occur with little or no intestinal ulceration in which solid food might be given early without ill effect, but in the absence of certain means of distinguishing such cases, and remembering unfortunate results which have occurred in some patients who have surreptitiously followed Dr. Barr's treatment, he thinks liquid food is the only justifiable mode of nourishment in the active stage of typhoid fever; and of all foods milk should be the staple diet, diluted with water, lime-water, or barley-water, according to the wish of the patient and the discretion of the medical attendant. Where milk so diluted fails it will be sometimes better taken peptonized; in some cases it is borne well when diluted with tea, and there seems no reason to deny a typhoid patient either tea or coffee. We give caffeine for the heart, tannin to check diarrhea, and allow sugar and water to be taken; why should a mixture of these be disallowed?

In some cases of vomiting or diarrhea, beef tea or meat extracts have to be substituted for milk. The quantity of milk given should be as much as the patient can digest without flatulence or colicky pain or curds in the stools. As a rule three pints is enough in the twenty-four hours, but the author sees no reason why more should not be given if the patient can take it well; persons often take five or six pints of milk a day under the Weir Mitchell treatment, and a patient wasting and losing blood rapidly, as in typhoid, will benefit by as much as he can take without digestive disturbance.

As regards stimulants the writer has nothing to add to the rules usually followed; they are not necessary as a routine part of treatment.

An important point is to secure sleep, and opium is quite admissible. Sir William Broadbent deprecates the use of chloral. In the treatment specially directed to cardiac weakness digitalis, strychnine, and caffeine are to be resorted to, but cardiac tonics receive little response from a heart with organically weakened muscle tissue; caffeine and strychnine act well together, but strychnine here, as in other conditions, may easily be pushed so far as to make the patient wakeful. Ether, ammonia, and sublimate, and diffusible stimulants, are often of use. Alcohol, no doubt, stimulates the heart, but if pressed too much has the contrary effect.

In all cases, and especially in some, endeavors should be made to keep up the volume and composition of the blood; sweats should be checked by belladonna or oxide of zinc or agaric acid, and diarrhea by enemas. There is no reason why cold water should not be given freely, due regard being had to preventing abdominal distention. In many cases ice-sponging or the cold bath contracts the vessels and lessens their relaxation for some time after its use, and possibly in the bath, or the tank, fluid is actually absorbed cutaneously. Raw meat juice and every form of nutriment possible must be given in cases of gradual weakness from blood deterioration, and the writer has sometimes given iron and malt extract. Oxygen inhalations are also of use. Solid food must be given as soon as it can be taken with safety; after three days without fever at any time in the twenty-four hours it may be given; it is best to intermit one day at first to ascertain if a rise of temperature is produced. In cases where it is deemed probable that little ulceration occurs the writer gives solid food earlier than in other cases. When cases drag on with little rises above the normal, solid food must be tentatively and gradually tried. In convalescence patients are hungry and require feeding up, and it is often in cases where solid food is long delayed that thrombosed veins occur.

When there are evidences of profound bloodlessness and weakness, whether following hemorrhage or not, saline injections may be of use. Personally, the author has found the subcutaneous injection of salines gives so much pain that he prefers injecting the saline fluid into the basilic vein. This flows in better with a simple cannula, drainage tube, and funnel than pumped in by the double-
action syringe made for the purpose. The writer has injected two pints, usually at a temperature of from 100° to 115°. After it there is usually sweating and rise of temperature temporarily. He believes the fluid should not be injected at so high a temperature as 105° in typhoid fever. In two cases the author thinks the patient’s recovery was due to it. In one of them, in 1866, the patient was in an apparently hopeless state of collapse, but recovered after two saline injections. Probably blood transfusion would be better, for in most cases saline injections only give temporary benefit.

Perforation may be accompanied by its well known symptoms, but in some cases of typhoid fever where nerve tone is already lost, and the tympanitic belly is soft and doughy, perforation and after-peritonitis may occur most insidiously, with little pain, collapse signs, or alterations in temperature.

Cases of recorded recovery from perforation based merely on evidence of symptoms cannot be taken as conclusive, for it may be simulated by rupture of peritoneum over a mesenteric gland and other causes; indeed, the abdomen has been opened for perforation in several cases where it had not occurred. In Herringham’s case nothing was found and the patient recovered; in Sheild’s case rupture of gall-bladder. In a case, however, recorded by Murchison a perforation had all but healed when erysipelas carried off the patient; and in a case at St. Mary’s Hospital in 1894 a post-mortem examination showed a perforation all but healed when the patient succumbed to septicemia. Three cases of twenty-two recorded operations for perforated typhoid ulcers have recovered, and as operation affords a better chance of recovery than that offered by Nature, it appears to be indicated in all cases in which perforation can be diagnosed—the difficulty in the diagnosis, however, will prevent the operation being very often performed. The only other treatment affording a chance of recovery is opium.

Some have regarded hemorrhage as a favorable occurrence in typhoid fever, and there is no amount of hemorrhage that may not be recovered from. In 1882 the author saw, with Dr. Wakefield, a patient who bled two chamberfuls, and recovered. But the more general opinion is that it is a bad omen, and that death follows thirty or forty per cent of cases of free hemorrhage, though sometimes long after the bleeding has occurred. It is generally arterial, but in a case of the writer’s in 1888 the necropsy showed that the dark blood had oozed away during life from a vein in the ileum, opened up by ulceration. In its treatment opium pressed freely, and turpentine, are useful, but often no drug is so efficacious as tincture of hamamelis; in one case in St. Mary’s Hospital in 1892 it checked the hemorrhage after all other remedies had failed, and is more to be relied upon than anything else—in five-minim doses in a little water every half-hour while the hemorrhage lasts, with or without opium. The application of the ice-bag to the abdomen seems beneficial, but it is depressing if kept on long after the hemorrhage has ceased; it freezes the abdominal wall into a leathery consistency, and probably interferes with the vitality of the subjacent intestine. The writer has repeatedly seen hemorrhage occur while the ice-bag had been on for days. The necessity for absolute non-movement of the patient when hemorrhage occurs is obvious.

In peritonitis without perforation opium is indicated.

Murchison in the edition of his work in 1862 wrote that diarrhea occurred in 96 out of 100 cases; in 1884 he found it reduced to 80 out of 100 cases; since that time it is much less frequent. Of 200 consecutive cases at St. Mary’s, diarrhea occurred in only 115; constipation in 48; and the diarrhea was seldom very severe. In many cases it had been set up by a purge given before a diagnosis was made. Diarrhea is found in a very large proportion of cases in which hemorrhage occurs, and in the writer’s opinion adds to the danger of typhoid fever by preventing absorption of nutriment and by draining the blood of fluid. He thinks purgative drugs should never be given, and diarrhea should be checked in every way possible by adapting the nature and quantity of food to the patient’s powers, by giving all food warmed, and by enemas of starch with or without opium rather than by drugs given by the mouth. Of the latter, salicylate of bismuth in doses of twenty or thirty grains three or four times a day is very useful.

Constipation must be treated if obstinate; enemas are better than purgative drugs for this purpose, and should have some disinfectant added to them. It is very important to overcome constipation before solid food is given; if not, it often sends up the temperature and an immediate recurrence of symptoms. Some attribute relapses to the giving of solid food, others to constipation. Cer-
tainly the two combined will produce a rise of temperature and disturbance for a considerable time, though not a true relapse with fresh spots. Tymanitis is commonest when there is much diarrhea. That form in which the belly is soft and doughy as well as swelled is due to general loss of nerve tone, and treatment affects it little. Diffusible stimulants, etc., may be tried. In the form of tymanitis with tense abdomen hot fomentations are preferable to the ice-bag. Passage of a long tube into the rectum gives relief and often sets up retention of urine.

In many cases swelling of abdomen is due not to true tymanitis but to stomach distention, the result of liquid food and the recumbent position. Food must be given in small quantities only.

Retention of urine must always be remembered; it is often overlooked in the general distention of abdomen, or because "overflow" occurs from the full bladder. Long retention may add uremic dangers in a typhoid patient very readily.

The question of moving a patient in cases where the sanitary conditions are bad has sometimes to be considered, for he will be likely if he remains where he is to take in fresh doses of the poison. On the other hand, as Sir William Jenner pointed out, the cases that do the worst owe it sometimes to having traveled when well on in the disease. If it is very early, careful removal will be best. If the patient is well on in the disease he had better remain where he is, as the risk of moving is too great.

In the third group the intercurrent affections of typhoid such as pneumonia are to be treated on ordinary principles; pneumonia is usually recovered from, and it is apt to begin or to end in the course of typhoid with abrupt rises of temperature or a critical fall, after which the typhoid temperature reasserts itself. Acute bronchitis in typhoid is more serious than pneumonia.

THE TREATMENT OF CHRONIC ECZEMA ON THE HANDS.

Edlefsen (Therapeutische Monatshefte, February, 1898) has found a successful mode of treatment of this disease. Eczema on the hands and fingers chiefly affects washwomen, and not infrequently women of the better classes. He orders a paint consisting of pure iodine o.1, iodide of potassium 0.25, glycerin 12 parts; the paint is applied every evening, and the hands are enveloped in lint. The irritation is always relieved, and in fourteen days the disease is generally cured. This treatment has been adopted with success in many cases where other remedies have failed. In the more obstinate cases boracic ointment was applied in the morning, and the iodine paint in the evening.

THE USE OF MYDRIATICS IN OPHTHALMIC SURGERY.

Ernest Clarke tells us in the Clinical Journal of November 28, 1898, that in all inflammations of the cornea, wounds of the cornea, and the severe inflammation of the conjunctiva, especially in phlyctenular conjunctivitis, a mydriatic is the most important part of the treatment. As previously shown, blepharitis and phlyctenular affections in children are almost always associated with some error of refraction which produces strain. This strain is removed by the paralysis of the ciliary muscles, and when the child is too young to wear glasses, atropine is the treatment.

Photophobia in children is at once lessened, and sometimes completely removed in a few hours, by the effective use of atropine, and especially is this the case when combined with cocaine. In older patients cocaine alone is very useful.

Again, the majority of cases of convergent squint in children are due to overaccommodation produced by hypermetropia; and if the child is too young for glasses, atropine prevents the ciliary muscle from being used, and thus lessen or cures the squint. In all forms of spasm of the accommodation mydriatics are invaluable.

In estimating errors of refraction it is of first importance to have the ciliary muscle at rest, and in all young patients atropine or homatropine must be used.

The mechanical effects of mydriatics are also of great importance; they are:

Prevention of synchiae in iritis and penetrating wounds or perforating ulcers of the cornea.

In certain operations, such as needling.

In central cataract, to enable the patient to see round the opacity.

To enable the surgeon to make a thorough examination to see lens and vitreous opacities, etc.

Mydriatics should not be used in acute glaucoma. The fluids secreted by the glands of the ciliary body nourish the various structures of the eye, and the greater part of this
fluid passes from the posterior chamber through the pupil into the anterior chamber, and thence out at the filtration angle into Schlemm’s canal. If this angle is not widely open the outflow is arrested. Dilatation of the pupil draws the iris into this angle, compresses the spaces of Fontana, and narrows Schlemm’s canal also; and thus increased tension or glaucoma may result from the use of atropine, especially in those predisposed, as hypermetropes and persons over fifty. Priestley Smith has shown that a small cornea and a shallow anterior chamber predispose to glaucoma. Unfortunately iritis and acute glaucoma are often mistaken for one another, and many a glaucoma which might have been cured in its early stage had it been recognized is treated with atropine, and the eye irretrievably lost.

The writer reminds his readers of certain signs which may help in distinguishing these two affections:

**ACUTE GLAUCOMA.**

- Increased tension.
- A dilated pupil.
- Pain very severe, not only in the eye, but in surrounding parts.

**IRITIS.**

- Tension normal.
- Pupil contracted.
- Pain less severe and more local.

In glaucoma secondary to iritis we generally do not see the acute form, and atropine will probably do little if any harm, as the pupil will probably not dilate because of adhesions. In such cases use homatropine carefully and watch the result; if the pupil dilates well, do not repeat it; and if the tension increases, use eserine.

If it is necessary to dilate the pupil of elderly people in order to make a more thorough examination of the lens, etc., it is wisest not to use atropine. Homatropine will answer the purpose just as well, and is much safer.

In perforating ulcer of the cornea eserine sometimes does more good than atropine, probably because it reduces the tension. If the ulcer is at the margin, on no account use atropine, as prolapse of the iris may result. The same advice applies to marginal wounds of the cornea.

In neuritis, retinitis, and retinal asthenopia mydriatics are contraindicated, because their use causes more light to enter the eye.

In what form should mydriatics be used?

Clarke believes the days of “drops” are over. It is impossible to know when using drops or solutions how much of the drug is absorbed, and how much is wasted. They produce toxic symptoms by passing down through the tear passages into the throat, and they do not keep well.

On the other hand, ophthalmic tablets and disks have been brought to such a state of perfection that they form the most scientific, efficient, and safe method of administering a mydriatic. The most useful tablets are: atropine \( \frac{1}{8} \) grain, and homatropine with cocaine \( \frac{1}{8} \) grain each.

Tablets or disks should dissolve quickly when placed on the inner surface of the lower lid, and should cause little or no irritation or pain.

**IS APPENDICITIS A SURGICAL DISEASE?**

Beck writes on this topic in the *New York Medical Journal* of November 26, 1898. He finally tells us that appendicitis is a surgical disease and should be treated surgically as soon as the diagnosis is made.

So long as no physician is able to ascertain the grade of bacterial virulence at its early stage, the safest therapy consists in the early removal of the appendix.

If the patient or his advisers should object to operation, the expectant immobilization treatment should be instituted, and, after the attack is over, the necessity of appendectomy should be made clear to the patient.

Should the conditions surrounding the patient be of an extremely unfavorable nature, should no competent surgeon be obtainable, and should there be other difficulties, the risk of the expectant treatment should be preferred to that of a badly performed operation in an acute attack. Then, if he should pass over the attack, the patient should submit to appendectomy later.

Considering that the mortality of simple appendectomy is almost nil, its performance should be urgently recommended to the patient after the first attack.

The writer well realizes that doing this will often cause the greatest difficulties to the family physician. So many prejudices, so many family considerations obtrude on him that he will often fail to have the courage to contend with the whole weight of his personality for these theses, although he is convinced of their scientific truth. Nor will Beck throw a stone at the family physician who, *jurare in verba magistri,* intoxicates himself with the music of internist statistics, and sneeringly shows the surgeon who advises operation the list of dissuading internists. He simply deplores things as they are, and adds his share to the better appreciation of a
disease which, to its full extent, is recognized by none of us yet. He hopes that the day will come when its surgical prospective will be everywhere acknowledged.

But he thinks that what we are entitled to demand imperatively from every one who undertakes treating appendicitis is that he learn enough of the pathology of the appendix to appreciate from the beginning the risk which the patient runs during his acute attack, and that information should be given accordingly. Penzoldt well says of appendicitis: "In none of these cases can a gloomy sensation of grave responsibility be suppressed. The physician who does not know this sensation does not know the nature of this disease."

THE PAINLESS TREATMENT OF CRACKS IN THE NIPPLES.

At the meeting of the Paris Obstetrical Society held on November 10, 1898, a paper was read by MM. Maygrier and R. Blondel upon the "Treatment of Forty Cases of Cracked Nipples at the Charité Hospital." They had dressed the cracks with orthoform, which brought about complete anesthesia during sucking and kept the cracks aseptic. The application of the powder causes only slight smarting. The infant was put to the breast a quarter of an hour afterwards and sucked eagerly, as orthoform has neither taste nor smell. The anesthesia persists for some time. MM. Maygrier and Blondel made trial of orthoform powder alone, of orthoform followed by a moist dressing of boric acid, and finally with a strong alcoholic solution of orthoform dropped into the cracks. They considered this last method the best, for it caused no more initial smarting, but it quite did away with infection of the breast, probably because the solution was able to penetrate into the recesses of the fissures.—Lancet, Nov. 19, 1898.

SODIUM BICARBONATE BY INTRAVENOUS INJECTION AS A PREVENTIVE OF DIABETIC COMA.

Some time last year Dr. R. Lepine published in the Lyon Médical an account of the case of a diabetic who had been in imminent danger of an attack of coma, but had been saved from it by an intravenous injection of three hundred grains of sodium bicarbonate. In the same journal of July 31, 1898, he records another instance of the successful employment of this device for warding off fatal coma. The patient was a man, thirty years old, whose diabetes was of unknown origin. He was very feeble, the patellar reflex was abolished, the pulse was frequent,
and Gerhardt’s reaction (a deep-red coloration of the urine on the addition of a little iron perchloride) was as intense as possible. His mean daily excretion of urine amounted to about five quarts; each quart contained a little more than seventy-five grains of urea and from nine hundred to a thousand grains of sugar. In view of the intensity of Gerhardt’s reaction, he was subjected to a pronounced alkaline treatment, being made to take daily nine hundred grains of sodium citrate and about a hundred and eighty grains of sodium bicarbonate. He was allowed leguminous vegetables in abundance. In spite of this treatment there was no improvement; the man lost weight, and on the 13th of July the depth and frequency of his respiration (thirty-two a minute) were striking, the pulse was 108, but there was no fever. The quantity of urine voided was smaller than usual.

In the presence of these symptoms, and thinking that within forty-eight hours the patient might fall into coma, Lepine lost no time in administering an intravenous injection of two quarts of sterilized water containing in solution three hundred grains of sodium bicarbonate. The infusion was conducted a little too rapidly, and in consequence, on auscultation of the heart, a galloping action of that organ was recognized, but there were no subjective cardiac symptoms, and the galloping ceased in a few minutes as the result of simple suspension of the infusion. The author thinks it was due to momentary overcharging of the ventricle. The results of the procedure were most satisfactory; the patient passed nearly six quarts of urine in the next twenty-four hours, and the pulse fell to 68. The man’s general condition was good and his appetite had returned. The amount of sugar in the urine was progressively augmented. The secretion remained acid, although its acidity was somewhat diminished. Lepine infers from the urinary analyses that the first effect of the infusion was a great elimination of salts of beta-oxybutyric acid. The acetonuria present in this case was less marked than it usually is in cases of the kind, but on the day after the infusion the urine contained over fifty grains of acetoone to the quart, and on the following day it contained less than a grain.

Of course, says M. Lepine, the patient was not cured, but he was evidently saved from an imminent attack of coma. His diabetes still persists, with all its possibilities.—New York Medical Journal, Nov. 5, 1898.

HEROIN.

Dreser (Therapeutische Monatshefte) says that heroin, the diacetic acid-ester of morphine, is a preparation which has been recently introduced, chiefly for the alleviation of cough and as a substitute for codeine, it being claimed that it is much more powerful than codeine in its effect as a respiratory sedative. It is stated, also, that while this is the fact its lethal dose is one hundred times greater than the efficient medicinal dose, while that of codeine is only ten times greater. The dose of heroin is one-third of a grain for the purpose named. It is also claimed for this new substance that while it allays abnormal irritability of the mucous membranes and so checks cough, it does not do so at the expense of depression of the respiratory center.

THE TREATMENT OF WHOOPING COUGH BY THE INHALATION OF MEDICATED OXYGEN.

In a thesis presented to the University of Paris, and quoted in the Gazette Hebdomadaire de Médecine et de Chirurgie of October 2, 1898, Dr. M. Lacroix gives the results of his experience in the treatment of twenty-five cases of pertussis by inhalations of oxygen medicated with certain antispasmodics. The substances used were bromoform, bromide of camphor, and cherry-laurel water. The apparatus employed consisted of a bag containing the oxygen to which is attached a rubber tube conducting the gas into a reservoir, which he calls the saturator. This reservoir contains pieces of pumice stone which are saturated with the medicaments to be used. From the reservoir is an outlet tube furnished with a bone mouthpiece. The pumice stone is placed in a glass and is saturated little by little with the medicaments, the whole being stirred the while with a glass rod. It is then replaced in the saturator, and at each sitting a pinch of bromide of camphor is added. When the stone fills the apparatus a tampon of absorbent wool slightly compressed, and intended to stop the aspiration of particles of pumice or bromide of camphor, is placed on top. When bromoform is used, it is previously dissolved in the cherry-laurel water. Dr. Lacroix uses ten grammes of each, but the quantity may be varied according to circumstances.

The mouthpiece is placed in the patient’s mouth, and a slight pressure of the oxygen bag sends the gas through the saturator, and
the gas thus becomes impregnated with the vapors. The taste of the mixture is said to be slightly disagreeable, but is nevertheless well tolerated by children. M. Coyon has treated at the Hôpital Trousseau over one hundred cases in this manner, without observing any pronounced dislike on the part of the patients. Dr. Dutremblay, on the other hand, finds a mask more convenient, and that method could be employed if the child refused to submit to treatment. The saturator needs renewal every four or five days.

About forty-eight quarts of oxygen is used daily in four inhalations, viz., twelve each time, about 8 A.M., midday, 4 P.M., and 8 P.M. The treatment is given without regard to either the access or the times of feeding. Dr. Dutremblay, however, divides the doses, and gives a few quarts of inhalation after each access, and this method would probably be advisable in private practice.

The advantages alleged for this treatment by Dr. Lacroix are:

It modifies the accesses of cough, diminishing them both in number and intensity.

It obviates complications, such as broncho-pneumonia, hernia, prolapse of the rectum, epistaxis, vomiting, constipation, fetid stools, etc.

It strengthens the organism, relieving the general condition, and placing the organism in good form to resist the invasion of infectious diseases so frequent after whooping-cough.

The method seems to commend itself as rational, not difficult of application, and well worthy of a trial in this obstinate and distressing malady.—New York Medical Journal, Nov. 5, 1898.

THE CONTROL OF HEMORRHAGE BY GELATIN.

Lancereaux and Paulesco employ the following solution:

1. Gelatin, 2¼ drachms;
   Sodium chloride, 2¼ drachms;
   Water, 1 quart.

This is sterilized, and from one to two ounces, which may be increased to three or four ounces, is injected underneath the skin of the thigh.

For combating the hemorrhage of tuberculosis it is stated that Huchard employs the following formula:

1. Gelatin, 2 drachms;
   Sodium chloride, 2¼ drachms;
   Water, 1 quart.

Dissolve with the aid of heat, filter, and sterilize.

Commence the injections in the quantity of one to two ounces under the skin of the abdomen. Where it is desired to produce coagulation of blood in an aneurismal sac we may employ the following solution, which is very much stronger:

- Gelatin, 30 grains;
- Sodium chloride, 2¼ drachms;
- Water, 3 ounces.

Of this they give one to two ounces subcutaneously.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC PROPERTIES OF PODOPHYLLIN, WITH SPECIAL REFERENCE TO INDIAN PODOPHYLLIN.

Mackenzie and Dixon contribute a paper with this title to the Edinburgh Medical Journal for November, 1898, and in concluding a description of their research they draw attention to the following points:

That Indian podophyllin is an active purgative and a useful therapeutic agent; that it may be substituted for Podophyllum pellatum; but it is important that the physician should know which sample he is prescribing, as the Indian variety is nearly twice as physiologically effective as the American.

That the active principles contained in the crude resin are two substances: (a) Crystalline podophyllotoxin; (b) podophyll resin—both of which act as excellent laxatives in small doses, without secondary constipation or other objectionable symptoms.

That although both these substances act very similarly on the alimentary tract, it is only the podophyll resin which exerts a true chologogic effect, which shows itself rather by a large increase of the solids secreted than by an increased quantity.

Both exert their specific activity when injected hypodermically in alcoholic solution, but in many so much irritation is produced as to forbid their employment in this manner.

THE THERAPEUTIC VALUE OF ANTI-STREPTOCOCCIC SERUM.

Dr. William Baum, of Chicago, read a paper on this subject before the Mississippi Valley Medical Association. Twenty-two cases have come under his observation in which the serum was used. Of these nineteen were erysipelas, one of erysipelas plus tubercular nuchal glands, one of facial erysipelas duringchildbed without septicemia, and one of erysipelas with puerperal septicemia and double labial abscess. The last
was the only fatal case. The serum used was supplied by Parke, Davis & Company.

The deductions he draws from an analysis of the literature and his own experience are:

In pure streptococcc infections the serum undoubtedly exercises a favorable influence on the course of the disease.

In the mixed infections the influence of the serum is noticeably demonstrable, but it merits further trial as an adjunct to other treatment.

Considering the grave character of the complications of a non-streptococcc nature reported, ordinary rules of therapeutics demand that in such cases, as with the diphtheria antitoxin, all indicated therapeutic procedures must be employed as well as the serum.

In view of the fact that erysipelas streptococci and phagocytes have been found to exist side by side in the lymph-channels, it is fair to assume that the influence of the serum is directly exerted bacteriologically on the streptococci and not entirely through a stimulation of phagocytic action.

The initial dose in all cases should be 20 cubic centimeters, to be followed by 10 or 15 cubic centimeters, according to the indications, every twenty-four hours.

Dr. Charles L. Minor said his experience is practically confined to secondary infections in tuberculosis. He has used the serum of Parke, Davis & Company with considerable satisfaction, and prefers it to Marmorek's.

_Southern Practitioner_, November, 1898.

**REMARKS ON DYSEPSIA AND A DIET.**

The _Edinburgh Medical Journal_ for November, 1898, contains an article by Gillespie in regard to this important theme, in which he states that he has been surprised at the frequency with which patients come complaining of some fancied disorder of the stomach, for which they have been treated in the usual manner, who prove on investigation to be suffering primarily from the metabolic misdeeds of bacteria in the bowel.

They undoubtedly presented symptoms of gastric disturbance, quite independent of hepatic troubles, while the state of the intestinal contents was usually but not invariably accompanied by autointoxication. By humoring the stomach with rest; with milk in small quantities and frequently, either in a natural condition or variously diluted and modified, thereby diminishing the number of bacteria admitted, or altering their species; by the use of calomel to destroy the bacterial forms in the contents of the duodenum and jejunum; of creosote, guaiacol, or other similar substances to deal with those in the ileum; and of salol to act on the microorganisms in the ileum and large intestine; by prohibiting all malt liquors and fortified wines; allowing, if stimulants are advisable, whiskey diluted to 4.5 per cent of alcoholic strength (one ounce with ten ounces of water), or champagne in moderate quantities—by such measures a rapid subsidence of all the symptoms is promoted. Cheese is often of benefit in this condition, given on each occasion in such amounts as the stomach can comfortably deal with. If this marvelously adaptable organ (considering the persistent ill-treatment, lay and medical, meted out to it) can digest cheese in fair quantities, its use may be pushed.

Shakespeare was sensible of the attributes of cheese in the process of digestion, and alludes humorously to it in "Troilus and Cressida" (Act ii, Scene 3), when he makes one of his characters exclaim: "Where, where!—Art thou come? Why, my cheese, my digestion, why hast thou not served thyself in to my table so many meals?"

Cheese is an excellent breeding-ground for many of the lowlier members of both the vegetable and the animal kingdoms. How can it, full of the organic agents of fermentation, check organic fermentative changes? Cheese undoubtedly possesses a considerable power of arresting or inhibiting those bacterial processes which are the actual agents in the production of intestinal dyspepsia, with its signs and symptoms—unless, indeed, it prove of too irritating a nature towards the mucous membrane of the alimentary tract. This power is due to the antagonistic properties of two classes of organisms.

It has been suggested in Germany with regard to the antifermentative action of cheese, and of kephir, that the carbohydrate moiety, although so small in such bodies, is the active antiseptic agent; the writer believes that the bacteria themselves form the pharmacological basis of the cheese prescription. The acids formed by these bacteria are inimical to putrefactive processes. The fermentation of the one class of organisms is incompatible with the fermentation caused by the other class. The great aim to strive for in excessive intestinal fermentation, alias putrefaction, is the destruction of the causal agents. Two methods are available—to forcibly drive them out of the bowel, or to
inhibit their growth in situ. These two methods should be used together. The first needs no further notice. The second may be carried out by the use of antiseptic drugs, by dietetic control of the bacteria swallowed, or by measures taken to raise the proportion of free hydrochloric acid in the stomach to a strength sufficient to inhibit the growth of, or prove fatal to, microorganisms partial to alkaline media, whether the acid-affecting forms are hindered by it or no. The ordinary conditions present in the contents of the bowel bear witness to the greater supply and prowess of the acid-fermentative agents. The reaction of the contents, save perhaps in a short portion of the lower end of the duodenum and upper part of the jejunum, probably is always acid, even if only slightly, in health—the cause, the metabolic processes of bacteria-producing organic acids as their natural output; the effect, a controlling influence over the growth of their kindred, but still rivals, the bacteria of putrefaction. The first class, as a rule, produce no poisonous substances, unless the alcohol they often form from carbohydrates be considered as such; the second class live largely on proteids, and, being extravagant by nature, use but little in support of their bodies, while manufacturing an excessive amount of unnecessary and nutritious substances to obtain that little.

Some experiments the writer has carried out on dogs seem to show that calomel acts upon the bacteria in the stomach contents, and in the higher parts of the small intestine; creosote and other antiseptic bodies of the same type act most powerfully below the jejunum; while the action of salol does not become marked until the middle of the ileum is reached. On testing the contents of progressive sections of the alimentary tract of the dog, killed two or three hours after the administration of a final dose of salol, no evidence of its decomposition could be obtained above the mid-ileum. Theoretically, salol is neither decomposed in nor absorbed from the stomach; experiment, however, has demonstrated that it can pass, presumably unchanged, through the stomach walls, and become altered in the blood, its derivatives appearing in the urine even if prevented from entrance into the gut. This has been shown in the dog. The duodenum was severed close to the stomach, and the pyloric end of the stomach pulled forward through the abdominal wall. Although it was impossible for the drug to reach the bowel, the dog’s urine contained salicylic acid, notwithstanding the complete failure of the test for that body in the contents of the stomach.

Calomel and salol, then, may be regarded as antiseptics acting in different spheres of influence. Usually it commences with a small dose of calomel, followed by a saline purge; and begin on the following day with eight-grain doses of salol thrice daily. A fact with regard to that drug is that the production of the perchloride of mercury, which must be the form through which it exerts an antiseptic action, and for which it is indebted to the hydrochloric acid of the gastric juice, does not appear to be proportionate to the size of the dose of subchloride. The transformation of a very minute portion of calomel into the perchloride is quite sufficient for all antiseptic requirements. After commencement of the salol treatment, a dietetic programme may be begun.

The writer has little or no faith in strict, hard and fast, empirical diets, and in this connection both gastric and intestinal dyspeptic conditions are alluded to. The habit of laying down unalterable dietetic rules, unalterable for indefinite periods—until the patient, maybe, gets well—leads to a practice of giving all patients who have any gastric trouble the same diet and the same limitations. Each dyspeptic is different from all others. Each case possesses some little idiosyncrasy, at least, which may profitably be taken into account. There is no doubt that many patients progress far more satisfactorily when they are entrusted with part of the responsibility for the proper conduct of their course of treatment, and when encouraged by a hope of achieving a return to normal health partly by their own endeavors.

ACTIVE CONSTITUENTS OF OLEORESIN OF MALE-FERN.

According to Professor Boehm, of Leipsic (Sudd. Apoth. Zeit.), the value of this preparation depends on the presence of aspidin, as well as that of filicic acid. Out of eleven preparations examined, six contained aspidin in large proportion (two to three per cent), while filicic acid was absent; four contained filicic acid, but no aspidin; and one contained small quantities of both. These results are of interest, as they apparently show that a high content of aspidin excludes the presence of filicic acid, and vice versa. Professor Boehm concludes after an experience of many years that an oleoresin containing principally aspidin is decidedly preferable to one rich in
THE TREATMENT OF URTICARIA.

The Journal de Médecine de Paris of November 13, 1898, recommends the administration internally every three hours of phosphate of sodium in doses of one drachm and asserts that this treatment causes a cure in twenty-four hours. Locally the following prescription, which is a favorite one in this country, is also suggested:

- Calamine and oxide of zinc, of each 1½ drachms;
- Carbolic acid, 30 minims;
- Lime-water, 2 ounces;
- Rose-water, 4 ounces.

To be used externally.

If the patient is a child the quantity of carbolic acid named above is usually decreased.

The phosphate of sodium is particularly useful in those cases of urticaria which have their origin in gastrointestinal disturbance.

Another treatment of urticaria quoted by the same journal is the injection of solutions of bicarbonate of sodium into the rectum. The formula which is employed is as follows:

- Bicarbonate of sodium, 5 drachms;
- Wine of opium, 30 minims;
- Boiled water, 1 pint.

These injections are given in the quantity of four ounces every few hours.

COCAINE SOLUTIONS.

The Journal des Praticiens states that Jonas has proved that aqueous solutions of hydrochlorate of cocaine do not have to be sterilized by heat for their preservation if one centigramme of salicylic acid is added to each ten grammes of liquid. A similar preparation is recommended by the British Pharmacopoeia composed of

- Hydrochlorate of cocaine, 15 grains;
- Distilled water, 2 ounces;
- Salicylic acid, 7 grains.

GALL-STONES IN THE COMMON DUCT CAUSING SIMPLE INFECTIVE CHOLANGIOTIS.

The Lancet of December 3, 1898, contains a paper by Hale White on this subject, in which he says something of its treatment. He does not think that in England there ought to be much difficulty about diagnosis from most other diseases, but in countries where severe malaria is common, and especially where it makes the patients yellow, the diagnosis may be very difficult, for the paroxysms and shiverings which characterize the disease under discussion very closely resemble ague, and, indeed, the diagnosis has sometimes been only satisfactorily made after finding the malarial parasite in the blood. But it may be very difficult to tell whether the gall-stone is setting up merely a simple infective cholangiitis, supplicative cholangiitis, or portal pyemia, for the diagnosis will rest upon the correct estimation of the severity of the symptoms. A very good example of this difficulty occurred in a woman, aged sixty years, whom the writer saw with Mr. A. G. Wells. She had rigors, an irregular high temperature, jaundice, a tender liver, and was desperately ill. The position was explained to her friends, and in the faint hope that it might turn out to be simple infective cholangiitis and that it might be possible to remove a stone, Mr. Arbuthnot Lane opened the abdomen, but could not reach the common duct because the parts were so matted from old local peritonitis due to gall-stones. At the post-mortem examination the writer found the liver studded with pyemic abscesses, a stone in the common duct, the biliary passages inflamed, and the lining membrane in places gangrenous.

The treatment of the patient the subject of this lecture gave rise to much discussion. Many urged that if the reporter thought there was a stone in the common duct setting up simple infective cholangiitis, he ought to have suggested an operation, but the following reasons prevented his doing this. If the case had been portal pyemia or supplicative cholangiitis, both of which were possible, an operation could do no possible good; if, on the other hand, the case were one of simple infective cholangiitis, we could safely wait to see what course the malady would take, for this disease is very chronic, and, badly off as patient was, she never, as far as her general strength went, appeared to lose ground. Then, too, it is a very difficult operation, especially when the liver is very large, to remove a stone from the common duct. In the case mentioned matting prevented Mr. Lane from even reaching the common duct. Out of Dr. Osler’s eight cases two were operated upon and both died. Waring quotes Jouard, who says that out of seventy-two cases operated upon and published up to 1895 twenty-
two died, and when we remember the inevitable tendency for more successful than unsuccessful cases to be published, that represents a mortality of about fifty per cent. Then, again, gall-stones are usually multiple, and even if we remove the offending one and any there may be in the gall-bladder, others will probably be formed later and passed down the duct. So that while the writer would most certainly not say that operation is never desirable, it is very important that we should hesitate for some time before embarking upon such a very difficult and dangerous operation. Probably we never ought to do it if the patient is keeping her ground, for there is always the possibility that she may pass the gall-stones into her duodenum. That fortunate result occurred in the writer's case, and owing to the size of the stones she has passed it is possible that her common duct is now sufficiently large to admit of the passage of subsequent stones, and as she wrote White recently that she appeared to be in good health and able to be up and about at her household duties, it is seen there is justification in not having advised operation. Since she left the hospital she has passed one other gall-stone without much difficulty. The course adopted of relieving pain, keeping her bowels open, and maintaining her strength appears to be justified by Dr. Osler's figures, for of his eight cases, two died after operation, two died from the effects of long-continued jaundice, three recovered without operation, and one passed out of observation.

To sum up, while the writer is far from saying that we should never advise operation, we should always watch the case before advising it, and not advise it if the patient is not losing ground.

THE TREATMENT OF ANEMIA DUE TO CONSTIPATION.

Dr. Van Valen (Medical News, Dec. 10, 1898) thinks the treatment should be specific. He considers that the most important thing in the treatment of constipation is the recognition of its cause. This is often in the stomach. In thirty cases examined chemically by him recently he found absence of all stomach secretion, though absolutely no symptom pointing to stomach trouble had been complained of. There was only diarrhea, and no wonder, since food was being passed on to the intestines in an absolutely unprepared state. Hypersecretion, especially hyperchlorhydria, led to constipation. For these cases Carlsbad salts is the very best remedy. They are purgative and also alkaline, and used for two or three weeks they give excellent results. Milk of magnesia is the next best remedy, and calcined magnesia might be employed with good results at times. Myasthenia of the stomach with failure of motility and dilatation, indicated by the well known splashing sounds, is often accompanied by myasthenia of the bowels. In these relaxed conditions with muscular degeneration there must be no laxatives used; they will only make matters worse; tonic, not irritant, treatment is required. After the stomach the liver should be thought of. If the stools are pale in color calomel in minute doses should be given—one-twelfth or one-fifteenth of a grain frequently repeated. When the trouble is in the small intestine the prominent symptoms are an increase in gas, a burning feeling, a sense of unrest, of oppression referred to the abdomen, and finally the presence of indican in the urine. This last is important. Water be thought of the greatest importance. Not enough water is drunk, especially in the cities, and two to six glasses of it should be prescribed between meals. This is often enough of itself to overcome the tendency to constipation. Of drugs he had found that rhubarb gives good results and does as little harm as possible. In myasthenic states particularly the tannic acid of the rhubarb tones up the muscular coat of the intestines. Of course, it should not be given to such an extent as to produce loose stools, as it will then inevitably be followed by constipation.

In spasmodic states of the intestine, of which ribbon-like stools is the pronounced symptom, some of the antispasmodics are to be used—for instance, hyoscymus in large doses, one to one and a half grains, or even to the production of slight toxic symptoms. Cascara when properly employed is an invaluable drug. Every one should have some fixed time when they go to stool. This should be when they are at leisure. It may be at any time—morning, noon, or night. The cascara should be given not three times a day as is often done, but in one dose so as to act at the desired time. The fluid extract of Parke, Davis & Co. has given him the best satisfaction. The dose must be decided for each patient and must be just enough to produce a formed, not a loose, stool. After ten days to two weeks the dose may be lessened by a drop or so every third night, not often,
and thus the patient gradually brought to do without its assistance.

As to fruit it does good as long as it does not increase gas formation, or produce burning feelings or diarrhea. If it occasions any of these symptoms it is not doing good.

THE EMPLOYMENT OF ICHTHYOL IN THE VULVAR PRURITUS OF PREGNANT WOMEN.

The Journal des Praticiens quotes Doisy as having employed this substance in this condition with great advantage after other methods of treatment had failed, as, for example, the use of chloralized water, carbolic acid, corrosive sublimate, menthol, and similar substances. The strength of the ointment used was about two drachms to the ounce.

EPISTAXIS: A SIMPLE METHOD OF TREATMENT IN SOME CASES.

Roche (British Medical Journal, Dec. 10, 1898) states that when astringents and other appliances are not at hand, the trial of the application to the back of the neck of very hot poultices is found useful in checking nosebleed. Linseed meal may be used to make the poultices, but any other heat-retaining material would do equally well. The rationale of the effect of the method is the effect produced on the vessels through the vasomotor system.

Many years ago Roche was asked to see an old lady whose nose had been bleeding for three hours. He found her very weak, and the bleeding not severe, but continuous. Local pressure and astringents had been tried without success. A very hot linseed poultice was applied to the back of the neck, and the bleeding at once stopped. The bleeding in her case was evidently due to degeneration of the coats of the blood-vessels; she had a rigid radial artery.

THE NON-MEDICAL TREATMENT OF CONSTIPATION.

A valuable article on this topic has been contributed by Lockwood to the Medical News of December 10, 1898. He thinks that the diet suitable for constipation may be divided into three classes: (1) Fecal-forming food: Coarse vegetables, coarse bread, cereals. (2) Secretion excitors: Sugars—milk-sugar, honey, fruits, compotes, salts, especially NoCl. (3) Peristalsis excitors: Cider, buttermilk, fats, organic acids.

Coarse vegetables, such as spinach, Brussels sprouts, turnips, and carrots, should constitute a large proportion of the diet. To avoid irritation of the stomach it is well to have them prepared in purée form. To this class of foods must be added the coarse cereals. The breads should be of coarse texture and should be given one day old. Porous bread is to be preferred. A very good biscuit is Dohl's dyspepsia cake, somewhat dry, but if moistened with hot water or milk and eaten with a little sugar, really not unpalatable. One biscuit at night is often serviceable without other dietetic rules. As to whether the taking of water with the meals is of benefit is a mooted point. There is no doubt that a glass of cold water on rising in the morning is of great service in increasing gastrointestinal peristalsis, but during the meals it is the writer's opinion that little water should be taken. In general the drier the diet the greater the mechanical stimulation of the intestinal wall. This constipation diet, in its entirety, is indicated in atonic constipation alone. Whenever inflammation exists bulky foods must be excluded and reliance placed on other foodstuffs and remedies. This bulky diet is also contraindicated in cases of muscular insufficiency of the stomach, especially with gastropitis, as the bulk of the food mechanically overloads the weakened stomach. In simple atonic constipation this diet, while theoretically indicated, can never be carried out in full severity by reason of objective disturbances (distention of stomach and intestines) and of flatulence. Such a diet, moreover, pays, so that meat and other articles of food must be allowed, to avoid monotony. This latter indication is most essential in neurotic patients, who require a varied diet. Care must be taken in all cases to exclude from the diet all constipating food. This is often overlooked. One glass of claret will neutralize, for example, the laxative effect of an entire meal. Tea must be freshly made and never strong.

It is not definitely proven whether the action of sugars is through the fermentation they undergo, producing butyric, lactic, and acetic acids, which increase intestinal peristalsis, or whether they act as do the salines, in producing a transudation of serum through the intestinal wall. Strauss and Boas incline to the latter theory. Certain it is that we have in this class of foodstuffs a very efficient means of combating constipation. Su-
sars are best given in the form of honey, milk-sugar, and fruit compotes. The simplest and best remedy the writer knows of is a tablespoonful of honey in half a glass of warm milk on rising in the morning. It very seldom disagrees or diminishes appetite for breakfast. Honey, jam, or marmalade may also be taken with the breakfast roll. Lactose (thirty cents per pound) is to be used instead of ordinary sugar for tea, coffee, and the like. Compotes of stewed fruit may be sweetened by it, and such a compote taken once a day at least. A very good combination is two parts of prunes and one of figs. Raw fruit he does not approve of. Huckleberries and cranberries are to be strenuously avoided. Diluted condensed milk may be used in place of ordinary milk.

Passing to liquids we have buttermilk, kumiss, and cider. Buttermilk is much lauded by German authorities, and has in the writer's experience proved very reliable. To secure good effects three glasses should be taken daily. Kumiss has a similar effect, somewhat increased by the stimulating effect of CO₂ on gastric and intestinal peristalsis. Kephir is not obtainable in our markets. White wines may be allowed in moderation.

Fats are indicated in large quantities, but their administration is somewhat difficult. The simplest form is to give butter, one-eighth to one-fourth pound daily. Cream seldom agrees. Cooked fats are of course injurious. In debilitated subjects cod-liver oil may be an excellent adjuvant. In young subjects the addition of fat to the diet may alone be sufficient.

Measures strengthening the abdominal wall consist of (1) massage, (2) abdominal gymnastics, (3) electricity, and (4) abdominal supports. Except in cases where constipation was dependent upon a neurasthenia, for which latter condition general, not local, massage proved of value, massage has been disappointing. This may be contrary to the general impression, but after extended and repeated trials the writer has abandoned a large measure of his previous hope in its efficacy. If ordered it should be given by an experienced operator. Massage is contraindicated in all inflammatory and spastic conditions.

Abdominal gymnastics are more serviceable. General exercise, especially bicycling and golf, are of great service, together with local exercises, such as the raising of the leg slowly to the vertical position and dropping it to the bed again.

Electricity has been a grievous disappointment to the writer. He has used faradism in a variety of ways, usually one broad electrode over the umbilicus, and a smaller one to the left of the spine at the level of the twelfth dorsal vertebra, but he has never been convinced of its utility. The results, however, are so good in atonic conditions of the stomach that he still continues hoping better things from it in intestinal work. Of galvanism he has not sufficient knowledge to speak. Lately, Boas has had great success in rectal faradism. One pole is inserted into the rectum; the other—flat electrode—is to be placed at various points over the colon. Boas claims brilliant success, and as he is a most conservative observer, great weight must be attached to his statements.

Artificial abdominal supports are indicated (1) in downward displacements of the stomach or colon; (2) in weakness of the abdominal wall or separation of the recti muscles. The supporter should always be adjusted before rising in the morning and worn continuously through the day. The most convenient apparatus is the Bardenhauer, made by the Pomeroy Truss Company, Fifteenth Street and Broadway, from the original Bardenhauer. In these cases the patient should be instructed to suspend the clothing from a corset-waist and not from the waist.

Hydrotherapy is a measure which must not be lightly passed over. The glass of cold water on rising has a well-known effect upon intestinal peristalsis, but its disadvantage is that it exerts a depressing effect upon gastric secretion.

The spinal douche Lockwood strongly recommends. While the patient sits in as hot water as can be borne, the spine is at first sponged with hot water, after which a pitcher of cold water is poured from a considerable height upon the back. Brisk friction should follow, and the hour of selection should be before breakfast. When the spinal douche cannot be given the patient may stand before two basins, one of hot and one of cold water, and alternately sponge the abdomen with the hot and cold. Such treatment is serviceable in atonic forms of constipation, but is contraindicated in inflammatory and spastic conditions.

Sedative remedies are indicated in conditions of intestinal spasm, a more frequent class of cases than is ordinarily supposed. In this type purgatives, massage, and bulky articles of diet are to be excluded, and a more soothing régime inaugurated. Atten-
tion should be paid to the primary cause, usually a hyperacidity of gastric contents. An efficient remedy in these cases, about which the writer speaks from considerable experience, is the Priessnitz Umschlag, or Neptune Girdle. Two thicknesses of flannel, large enough to cover the abdomen, are wrung out in hot water, covered by oiled silk, and applied to the abdomen at night by means of a binder. The soothing effect of a nocturnal bath is often of service. Small doses of sodium bromide and belladonna, preferably with chloroform water as a vehicle, may be necessary in obstinate cases.

Oil irrigations were first employed by Kussmaul, and are generally known by his name in German literature. The results personally seen in Boas' clinic and in the writer's own practice have been so brilliant that he is inclined to attach much importance to this form of treatment. A rectal tube of large caliber, with a large lateral opening, is introduced six to eight inches into the rectum, and from six to eight ounces of a bland oil allowed to enter slowly. Cottonseed oil free from rancid acidity is as satisfactory as olive oil, and is inexpensive. In Boas' and in Pick's clinics the patient assumes the knee-chest position. The author's modification of this is more agreeable to sensitive patients.

The patient receives the injection while in the Sims position, with the hips elevated on two pillows, and with the muscles well relaxed; he remains so placed for ten minutes, when the dorsal decubitus is assumed for ten minutes, after which the patient lies for ten minutes on the right side, the hips still being elevated. By this method the oil reaches throughout the entire length of the colon. No immediate results occur, as a rule, and the patient may go about his daily work, although the injection is to be given by preference at bedtime. In the great majority of instances the patient will have one normal movement for three to five successive mornings without straining. The action of the oil seems to be due to the fact that the intimate commingling of the oil with the feces prevents all further drying processes, thus markedly facilitating the outward passage of the feces, and in presenting a greater bulk to the expulsive efforts of the rectum. Pick recommends daily inspection of the stools and a repetition of the injection whenever the oil disappears from the feces. It is just as well, however, to rely upon clinical data, and to repeat the treatment whenever the effects of the previous injection have subsided. Ordinarily, every five days is sufficient. One great advantage of this method is that it may be used in atonic, spastic, and inflammatory conditions alike.

THE MANAGEMENT OF THE FEVER OF PNEUMONIA.

A very useful and practical debate on this subject has recently been held in the Section of Pediatrics of the New York Academy of Medicine, and is reported in the Medical News of November 19, 1898.

Chapin thinks that in our management of hyperpyrexia the first point is to avoid any measures that will secondarily have a bad effect, and thus hinder future chances of recovery. All depressing remedies come under this head, as, for example, most of the coal-tar derivatives. The only exception to this rule is the occasional administration of small doses of phenacetine in atonic cases where there is pain and nervous restlessness. Cardiac stimulants, such as caffeine or camphor, are always added. When very high temperature keeps recurring, however, this remedy is not to be continued. Antipyrin, and especially acetanilid, should not be given under any circumstances. It is sometimes a great temptation to give these preparations, as they are easily taken and usually have a prompt if only temporary effect. The application of water is on the whole the safest and most satisfactory method of controlling dangerous hyperpyrexia. Much may be accomplished by a thorough application of cold to the head. This not only reduces the temperature, but relieves to a certain extent its deleterious effect upon the brain and nervous system. In order to be effectual the cold to the head must be thoroughly and continuously applied. The ordinary method of applying cool cloths is not sufficient. Finely cracked ice placed in bladders, from which the surplus air is expelled, may be molded around the head, especially at the vertex and occiput. Chapin has found ice poultices, made by mixing finely cracked ice with flaxseed meal in oiled silk, placed around and on top of the head, to be most valuable. By this means a steady application of cold can be conveniently applied. If this is not accomplished, the next resource is the application of compresses directly to the chest. The child is stripped, wrapped in a blanket, and placed upon a table. A stimulant is given and the feet are placed in contact with hot bottles.
A compress sufficiently large to surround the chest is plunged into water at a temperature of from 70° to 95° F., and applied to the chest. This is changed every ten or fifteen minutes until the desired result is obtained. In order to disturb the child as little as possible, the nurse is directed to apply the compress from the front, tucking in the ends until they meet in the back, in this way avoiding much movement or inconvenience to the child. The exact temperature of the water in a given case must be determined by the condition of the child, and the temperature to be combated. A needless amount of cold is often employed. If the temperature is 105° F., the water may be 95° F., or even warmer, at the start. A frequent application of the compresses will often produce results at this comparatively high temperature. If the compresses are allowed to remain unchanged, they become warm and the effect is lost.

If the temperature does not yield, the temperature of the water can be lowered until it reaches 70° F., 60° F., or even lower. It requires some careful watching to determine exactly how low the temperature of the water may be kept. The addition of about one-fourth part of alcohol sometimes increases the value of these compresses. This was well exemplified in a case recently under the author's care. An infant fifteen months old with an extensive bronchopneumonia had a temperature ranging from 104° F. to 105° F. As the symptoms were somewhat urgent, the infant twitching as in beginning convulsions, a compress at 60° F. was applied about the chest. The child became slightly cyanotic under the compress, without much reduction of temperature. It was then removed and stimulants given. The following day compresses at 70° F., with the addition of one-fourth part alcohol, were applied, and the child reacted well to this treatment; the temperature soon dropped to 102° F. So long as the feet and hands are kept warm the cool compresses may be applied, but chilliness of these parts is a contraindication to cold. When the temperature is reduced to 102° or 103° F., the compresses should not be renewed, but are kept in position in case the temperature ascends again to an unsafe degree. In the meantime they act in the same way as a cotton-batting jacket. Chapin has sometimes kept a child in this position for several days, applying cold when indicated by a hyperpyrexia, which tends to recur. This clinical fact is probably explained by a mixed infection, and not the pneumococcus alone, being responsible for the disease. Wide variations in the temperature point to the former condition.

The deepened respirations ensuing upon the application of the compresses have a favorable effect upon the pneumonic circulation. As a rule children do not object to the compress when applied in the manner here suggested, the principal point being to avoid too great a degree of cold and to apply the compress with as little disturbance as possible to the child, keeping the extremities warm.

Although Chapin has occasionally employed the tub he rarely uses this method now in combating hyperpyrexia. The fright of the child and the exhaustion which accompanies the tubbing contraindicate its use. He believes that all the good effects which may be obtained by the use of the tub may be had by a proper use of cool compresses. In case of cyanotic children, with prostration and hyperpyrexia, he has employed the warm bath (100° F.) with friction of the surface with good results.

Continuing the debate Holt spoke of the treatment of pneumonia in very young children. By way of summary he lays stress upon the following points in the treatment of pneumonia in this class of patients:

- No depleting measures are ever admissible.
- Hygienic treatment, including fresh air, proper feeding, and intelligent care, is of the utmost importance.
- No unnecessary medication should be permitted.
- Many annoying symptoms may be relieved by local treatment, such as the cough by inhalations, pain by counter-irritation, restlessness by the ice-cap or sponging.
- Stimulants should be deferred until demanded by the condition of the pulse.
- High temperature is much more safely and effectively controlled by the use of cold than by drugs.
- Greater caution is necessary in the use of powerful stimulants than is generally observed.

Rest is quite as important as in other serious diseases.

Dr. Simon Baruch next discussed the value of hydrotherapy in the pneumonia of children. He said that the short time at his disposal would not permit him to offer more than a general outline of the hydriatic procedures which he had found useful, and to inculcate the necessity of using each with due regard to its rationale. In children under
three years, the tub-bath with continuous friction is most useful. If the body temperature is between 101° and 103° F., a tub is placed upon two chairs, near the bed, and half filled with water at 95° F.; and the trunk is gently submerged and held by pressing the fingers upon one shoulder (not upon the chest). Ice-water is now added, without being allowed to touch the child’s body, until 85° F. is reached; friction over the entire body is maintained for five minutes.

This is a good initiatory procedure; it may be repeated every four to six hours with advantage so long as the temperature does not fall below 101° F. When the body temperature is above 103° F. the bath water may be reduced to 80° F., very rarely lower, and never so low as some bath temperatures mentioned. The duration should be prolonged to eight minutes; in this event it requires repetition every four hours. In the intervals between the baths a compress, covering the entire anterior part of the trunk, consisting of three folds of old linen or a towel (without fringes), wrung more or less out of water at 70° F., and secured by a flannel bandage placed around the body, may be applied with advantage every hour when the patient is not asleep. This procedure not only fulfils every indication, but it also renders the demand for bathing less frequent.

When delirium and stupor are present, when cyanosis is pronounced, and cardiac action embarrassed, when the bronchi are clogged with secretions, increasing dyspnea, in these conditions, which are so frequent in bronchopneumonia of children, the full bath may be changed to dips into water at 80° F. or less for a few seconds, repeated two or three times in rapid succession every hour, the temperature, duration, and frequency being in accord with existing conditions. An excellent procedure in these desperate cases is the affusion with basins of water at 60° F. or less, poured over the head and shoulders of the patient, who is held semi-recumbent in a tub containing water at 100° F. Rapid drying and friction are demanded after these procedures, because the patient’s reactive capacity is below par. Body temperature is not an index for the cold affusion, which should be given in these desperate cases even if the temperature is low. We aim to stimulate the central nervous system and thereby improve the circulation, respiration, and expectoration. When the child is restless, an occasional full bath at 95° F., prolonged for ten minutes, will prove soothing.

In most children over three years of age full baths are too disturbing. A younger child will become quiet as soon as it experiences relief and comfort, while the older child will continue to struggle and scream. Whenever the child is tractable he prefers the full bath, but he insists upon it in every case when other treatment proves inadequate. Having observed that the toxins of pneumonia endow the patient with less resistance to cooling procedures than do the toxins of typhoid fever, he avoids full baths colder than 75° and longer than eight minutes in the former disease. In the management of pneumonia patients larger reductions of the body temperature are not the prime object.

In most children above three years of age the chest compress consisting of three folds of old linen so arranged by slits in the axillary portion as to fit snugly around the chest down to the navel and held in position by a flannel binder, is the most useful procedure. The linen is wrung out of water at 65° to 70° F., more or less thoroughly, according to the temperature and general condition, and the flannel bandage is pinned over it. (Oiled silk, which the nurse will recommend for protection of the bed, counteracts the object of this compress and converts it into a poultice.) It is repeated every hour and discontinued when the temperature reaches 100° F.

These are the simplest and most useful hydriatic procedures in the pneumonia of children. The time limit precludes their more detailed description.

Baruch concluded with a few words of warning to the effect that spontaneous reaction must always be provided for by friction during the bath so that there should be no need for warmth and friction after the bath. Whenever the patient becomes very chilly, with chattering teeth and cyanosed face, we may conclude that the procedure has been faulty and must be modified. A few nights ago Baruch saw a case in consultation with a well-informed practitioner who feared water-treatment because the patient had become cold and cyanotic under a wet pack. Inquiry elicited the fact that the patient had been simply wrapped in a cold, wet sheet (no definite temperature). She was not covered snugly by blankets, as is demanded by the technique of the wet pack, in order to promote reaction.
This incident illustrates the importance of correct technique. Reaction is always furthered by rubbing during the procedure, or by protection against evaporation. It may be enhanced, also, by modifying the temperature of the water, not, as is often erroneously done, by elevating it, but by lowering it within reasonable limits, and shortening the procedure. It is a law of hydrotherapeutics that low water temperature, strong mechanical impact, and brief duration promote reaction. Higher bath temperatures are more agreeable and, if the procedure be prolonged, afford greater temperature reduction, but do not produce the stimulating, antifebrile effect of a correctly adapted cold procedure.

CANCER OF THE TONGUE.

H. Küttnner (Quarterly Medical Journal, October, 1898; Beiträge z. Klin. Chir., Bd. xxi, Heft 3) has conducted several experiments upon the dead body with regard to the anatomy of the lymph vessels and lymph glands of the tongue. His conclusions are as follows: The tongue is extraordinarily rich in lymphatics; the lymph from one-half of the tongue flows to the glands on both sides of the neck; the lymph vessels of the overlying mucous membrane and that of the deeper layers have the same outlet; the lymphatics are very numerous and form many anastomoses; the lymph glands of the tongue are the submaxillary glands, the deep cervical glands over the jugular veins, small lingual glands, and glands in the musculature of the tongue which are placed between the genioglossi muscles. There are also direct lymph connections between the tongue and the supraclavicular glands. The final branch of the deep cervical glands can, at least on the left side, open directly into the great veins. The submental glands, the glands at the lower end of the parotid, and the superficial cervical glands do not receive lymph from the tongue, but one observation showed that they were connected with the deep cervical and submaxillary glands.

The salivary glands may become infected by direct invasion from contiguous lymphatic vessels or glands, and they may become infected by the blood-stream. In lingual cancer, as in mammary carcinoma, the glands should be looked upon as infected and completely cleared out. The submaxillary, submental, and deep cervical glands on both sides should be removed, and even clearing out should be extended to the clavicle. If enlarged glands can be felt in the supraclavicular fossa, they should be removed.

Küttner recommends the following incisions: a median cut running from the chin to the sternum, and a somewhat concave incision running from the angle of one jaw across the hyoid bone to the angle of the jaw on the opposite side. Four flaps are thus formed which can be turned backwards.

ANEURISM OF THE UTERINE ARTERY CURED BY LIGATION OF THE INTERNAL ILIAC ARTERY.

Mundé (Medical Record, Dec. 31, 1898) reports the case of a patient who, after having an abscess in the left vaginal vault opened, developed an aneurism the size of a hen's egg, close to the cervix and extending slightly down on the left vaginal wall. He made a four-inch incision in the left semilunar line, opening the abdomen in Trendelenburg's position, and after some difficulty in isolating the artery, especially from the ureter, which crosses it and lies close to the inside of it, ligated the internal iliac artery. Pulsation of the aneurism ceased entirely. The recovery was uneventful.

RETROPERITONEAL HERNIA: WITH A CASE OF RECOVERY AFTER OPERATION.

Tubby (Medical Press, Sept. 7, 1898) says that the varieties of retroperitoneal hernia have been described by Treitz under three headings: those into the fossa duodeno-jejunalis, where a pouch of peritoneum is sometimes met with behind the inferior mesenteric artery as it curves towards the left side; into the fossa intersigmoidea; and into the fossa subcecalis. More recently the subject has been amplified by Mr. C. B. Lockwood. A case of retroperitoneal hernia into a pouch behind the superior mesenteric artery is found described in the eighteenth volume of the Transactions of the Pathological Society. The following case was one of hernia into the fossa duodeno-jejunalis behind the inferior mesenteric artery.

On February 27 of this year (1898) Tubby was called to see Mrs. W., aged sixty. Details of previous history are as follows: Eight years ago she had a definite attack of gallbladder colic and then passed several gallstones. They were multifaceted. A week before operation she was doing a good deal of lifting. On February 23 Dr. Burrell was
called in to see her for what she described as internal chill; she complained of a dull aching pain with some shivering. The temperature was normal; pulse 90, full, and regular. The pain was specially referred to the gall-bladder and was of a dull, gnawing character. Slight trace of albumen in urine, which might have been due to chronic cystitis. On February 25 she was given pil. hydrag., gr. ij, and tinct. opii, mi. x, every four hours for pain. She felt better, but her bowels were not open, so she was given half an ounce of castor oil, with no result. At 5 P.M. on February 26 she began to complain of violent pain, and the abdomen was noted to be much distended and hard, with distinctly increased dulness in the right hypogastric region. The pulse was very quick and not of good quality. There was no vomiting, but some nausea. Mrs. W. said that she had had three attacks of pain previous to last attack, but not so severe, and was inclined to put it down to "liver trouble." When Tubby saw her she complained of intense pain, especially in the right iliac fossa. There was great distention of the lower part of the abdomen; some dulness in the right flank; the legs were not drawn up; pulse 102 and regular; breathing costal. Seen again at 11 p.m. same night, the abdominal distention had doubled, the pulse was thready and irregular, the pain and tenderness were still more marked, and she had vomited.

It appeared that the symptoms might arise from impacted gall-stones, so operation was immediately performed. When the abdomen was opened numerous distended coils of intestine appeared, and there was a considerable amount of flaky fluid in the flanks. The whole length of the small intestine was carefully examined for impacted calculus, but none was found. In the course of examination a retroperitoneal hernia into the fossa duodeno-jejunalis was discovered. There was a coil of small intestine firmly lodged in it, being derived from the lower part of the ileum, within one and a half feet of the ileocecal valve. The portion was withdrawn with very considerable difficulty, as the intestine was very much distended and dark in color. The peritoneal fluid was sponged out, the cavity was rendered dry, and the wound was sewn up. The after progress of the case was uninterruptedly good. On March 1 she had two evacuations, and the wound had almost closed by primary union. Her subsequent course was extremely good. It was noted at the time of operation that the gall-bladder was small and hard, and appeared to contain many calculi; but the patient's condition was such that it was not advisable to perform a cholecystotomy on account of the danger of collapse.

The points of interest in this case are the nature of the history and the rapid onset of symptoms simulating impacted gall-stone. The fact that the retroperitoneal hernia involved the lower part of small intestine accounts for the extremely rapid distention of the abdomen and the signs of absolute obstruction. Another point of interest was the great difficulty experienced in withdrawing the distended intestine from behind the inferior mesenteric artery; great gentleness and patience had to be exercised in so doing.

There can be no doubt that the promptness with which operation was consented to, and was carried out, was the important factor in saving her life.

A FURTHER CONTRIBUTION TO THE SURGERY OF STONES IN THE BLADDER, BASED ON A RECENT SERIES OF CASES IN HOSPITAL AND PRIVATE PRACTICE.

Reginald Harrison (The Lancet, Nov. 12, 1898) says that the cases have all been operated upon either in hospital or private practice during the interval of 1890 to 1897, and include every instance thus dealt with during this period. Six of the 101 litholapaxies terminated fatally: (1) A man aged sixty-five, operated upon successfully on the first occasion, died on the third day after a repeated operation, which was performed thirteen months subsequently. The kidneys were extensively involved in supplicative nephritis. The stone was a phosphatic one weighing close on two ounces. Repetition of the operation had clearly been delayed too long. (2) A man, aged sixty years, died on the twenty-eighth day after operation from chronic supplicative nephritis and syncope. (3) A man, aged seventy-two years, died on the sixth day after operation from pelvic cellulitis, probably due to suppuration within a vesical sac or pouch. (4) A man, aged fifty-four, was operated upon successfully on the first occasion, but died after a similar operation, repeated fifteen months later, from supplicative nephritis caused by a chronic urethral stricture which had gradually contracted. Had a perineal lithotomy with division of the stricture and drainage of the bladder and ureters been practiced on the second occasion he would have had a
better chance of recovery. The patient derived so much relief from the first operation that he wished it repeated on precisely the same lines. (5) A man, aged sixty-two years, died on the tenth day after operation from extensive supplicative nephritis consequent on urethral stricture of some years' standing. He was much exhausted from many weeks' traveling under painful circumstances. (6) The remaining fatal case was that of a man aged seventy-six years. He died on the twenty-ninth day after what promised to be a very successful operation. A large urate stone was crushed and evacuated, the dried fragments of which weighed 975 grains. The prostate was much enlarged. The calculus had previously caused him great pain, and the operation afforded complete relief from this. He died from senile decay.

Of the 101 different persons included in the table and who were subjected to litholapaxy, twenty-three were known to have one or more recurrences, for which they were treated on subsequent occasions. In these twenty-three persons who had recurrence of stone after crushing litholapaxy was repeated once in thirteen of them, twice in two, thrice in one, four times in one, five times in one, six times in one, nine times in two, and ten times in two, making a total of 174 litholapaxies in 101 individuals, with six deaths.

In several of the repeated operations the proceeding resolved itself into occasionally removing from the bladder calculous concretions with the aid of the lithotrite and aspirator, much on the same principle as a dentist removes tartar which has collected about the irregularities of the teeth. These occurred for the most part in elderly men with atonic bladders who were more or less dependent on their catheters, and possessed but little power of voluntary expulsion. To submit these cases to a cutting operation for the purpose of removing concretions and draining the bladder could not be recommended, as during intervals, sometimes extending over many months, they enjoyed fair, and even active, health.

As in records by other surgeons which have been recently published, mortality connected with all these proceedings had been reduced to so small a percentage as to assimilate them in this respect to those which we are accustomed to speak of as minor or non-fatal operations. The period of convalescence has also been considerably lessened. In both of these important respects there has been generally a remarkable diminution.

Excluding three or four young persons about or below puberty, the average age of the patients was over sixty-two years. Nor is it difficult to understand why this should be. Enlarged prostate not only often renders the act of complete micturition mechanically difficult and impossible, but it furnishes favorable local conditions for the growth of stones, which, having descended from the kidney, are thus detained there. Under such circumstances the male bladder may not inaply be regarded as a bedding-out ground for renal calculi. Many instances in this series serve to illustrate this and to show how gravel and calculi which were formerly expelled naturally ceased to be so as soon as the prostatic age had been reached. And what applies to kidney calculi and concreted crystals is equally true of other foreign bodies which a chronically inflamed bladder is apt to contain. That an incomplete removal of the débris after a crushing operation may be responsible for some recurrences there can be no doubt, but not to the same extent as some are disposed to consider. A red urate or a black oxalate stone is sometimes supplanted by a pure white phosphate. More than one recurring calculus which has been removed had a fixed origin on the rough cicatrix of a previous suprapubic cystotomy; two were formed on centers furnished by the remains of silk sutures employed in the latter operations, and others have had their origin on nuclei provided by shreds and sloughs from an inflamed bladder. Further, the sacs and pouches of bladder distorted in this way by prostatic obstruction furnish hiding-places for débris which are almost inaccessible. In view of such obstacles and to prevent recurrence taking place much importance must be attached to the thorough clearance of the bladder in the first instance, to the subsequent management of the case after it has left the hands of the operator, and to such measures as have for their object bringing about shrinking or atrophy of the enlarged gland.

The lithotrites employed should be capable of rapidly and completely breaking up the stone without pounding it too much into such masses as a pestle and mortar produce. The jaws of the lithotrite whilst protected should be able to cut up stones such as the phosphates, which though soft and friable are apt, when mixed with the mucus from the bladder, to run into tough pulvaceous pieces which may readily be left behind and form nuclei for further concretions. Hence the
powerful fenestrated lithotrites are, as a rule, to be preferred.

In cases complicated with prostatic enlargement, and where the patient is, as is often the case, more or less dependent upon the catheter, the bladder should be attended to for some time after operation. Sufficient importance is not attached to this point. If these cases were carefully looked after three or four months after the operation, recurrences would be far less frequent. At least once a week the bladder should be washed out with the metal catheter and aspirator, as used in connection with the operation, in addition to such irrigation and catheterism as the patient can himself employ when necessary.

The effect of silver nitrate as a local application in cases of chronic cystitis with prostatic enlargement where there is a tendency to produce phosphatic concretion is well known. There was a case some years ago which bears importantly upon this practice—that of an elderly man who when suffering from residual urine broke a gum-elastic catheter whilst passing it and left several inches of it in the bladder. The general condition was such that no immediate steps could be taken to remove it, and it was therefore advised that the bladder should be washed out twice a day with a weak solution of silver nitrate. This was done, and ten days afterward the patient allowed Harrison to extract the broken portion entire with the smooth-bladed lithotrite. Neither on the piece of the catheter nor within the bladder was any sign of phosphatic concretion. The nitrate, as do other salts that may be artificially introduced into the bladder, prevented molecular coalescence taking place, as the urine was alkaline and offensive during the ten days the catheter remained in the bladder.

Vasectomy was resorted to under these circumstances in instances where in addition to recurrence of stones serious symptoms of prostatic obstruction existed. The stone having been removed in the usual way by the lithotrite and aspirator, one was resected, and seven days afterwards the remaining one was treated in the same manner, about an inch of each tube being taken away. The small wound usually heals under a collodion dressing in forty-eight hours.

Further experience and a still more extended period of observation will warrant the conclusion that the diminishing number of recurrences in this series was due not entirely to any additional pains taken in the first instance in the removal of stone, but partly also to the use for some time after of the evacuating catheter and wash-bottle, and to the employment of vasectomy on recurrence in suitable cases, where there was much prostatic enlargement.

The chief points in favor of the selection of perineal lithotry appear to be these: (1) It enables the operator to crush and evacuate large stones in a short space of time; (2) it is attended with very small risk to life as compared with other operations, such as lateral or suprapubic lithotomy, and is well adapted to old and feeble subjects when for any reason crushing is inadmissible; (3) it permits the operator to wash out the bladder and any pouches connected with it more effectually than by the urethra, and the route is shorter and the evacuating catheters employed are of much larger caliber; (4) the surgeon can usually ascertain, either by exploration with the finger or by introduction of forceps into the bladder, that the viscus is cleared of all débris; (5) it enables the surgeon to deal with certain forms of prostatic outgrowth and obstruction complicated with atony of the bladder in such a way as to secure not only removal of the stone but restoration of the function of micturition; and (6) by subsequent introduction and temporary retention of a soft-rubber drainage tube the states of cystitis due to retention of urine in pouches and depressions in the bladder wall are either entirely cured or are permanently improved. To lock up unhealthy ammoniacal urine after a lithotry in a bladder which cannot properly empty itself is to court formation or recurrence of a phosphatic stone. Hence it is well suited to some cases of recurrent calculus. He has never known a wound to remain unhealed except in those instances where for some reason or other it has been desired to construct a low-level urethra.

Harrison is not much in favor of suprapubic lithotomy as a means of removing large calculi from elderly males. In younger persons it is much more safe and there is less objection to it. The mortality is considerable, as shown by Guyon, in males over fifty years of age. The cicatrix which is left in the bladder sometimes greatly interferes with complete micturition, and in two instances a rough scar was shown, on exploration, as forming a holding-ground for phosphatic concretions. In one of these instances the scar has been excised with advantage.

Nitrous oxide gas and ether were the anes-
theetrics usually employed throughout the whole series of operations. In elderly and debilitated persons with weak hearts the stimulating effect of ether in improving circulation was often most marked; nor were any casualties noted in connection either with instruments used or parts operated upon. No serious hemorrhage was encountered where incisions were necessary, and after the litholapaxy it was rare to find the urine tinged with blood forty eight hours after operation. Any cystitis which was present at the time of operation usually rapidly subsided after removal of the stone, and no trouble with elevations in temperature, rigors, or fever complicated recovery.

As to sounding for stone, it is much better for stone to be removed where this is practicable on the occasion when it is first detected by sound and the diagnosis is made. This practice predominated in this series. Where the prostate is large stones grow up like mushrooms in the pouch-like space between the large prostate and the back of the bladder, and make as it were nests for themselves. Where there are two or three they often become fitted to each other like tesselated tiles, and if this arrangement is accidentally and suddenly disturbed most acute cystitis is apt to follow. Most of us know how much discomfort a displaced piece of tartar will cause in the mouth until it is completely removed. Even when they are delicately and lightly touched with the sound the stones may get out of gear with their bed, and if urine finds its way underneath them to some unaccustomed spot, an acute cystitis may be aroused in the interval between the detection of the stone with the sound and its removal by the lithotrite.

In conclusion, this series of cases may serve to illustrate: (1) conditions under which the surgical treatment of stone in the bladder, in the adult male particularly, have to be undertaken, at all events in this country; and (2) various operations which may be selected for its cure or relief. Of course the relative proportions of the latter to each other will vary in some degree, and it is only reasonable that this should be expected.

ON EXCISION OF THE GASSERIAN GANGLION FOR TRIGEMINAL NEURALGIA.

J. Hutchinson, Jun. (British Medical Journal, Nov. 5, 1898), notes that there are at present practically only two methods of approaching the ganglion: one from below—that is, through the base of the skull after resection of the zygoma and some parts of the lower jaw (Kocher, Rose, etc.), which may be termed the pterygoid route; the other from the outer side through the temporal fossa (the temporal route). Between these two methods the time has come for a definite decision to be made. The temporal route possesses the following amongst other advantages:

1. A short skin incision and comparatively small division of muscles; the cicatrix will probably be so hidden by the scalp as to be found with difficulty. Beyond some slight flattening from wasting of the temporal and masseter muscles, there is no disfigurement whatever resulting in the face.

2. The ganglion can be clearly exposed with but slight risk of opening the subarachnoid space.

3. The only part of the skull divided is the squamous portion of the temporal bone.

4. There is no risk whatever of making the wound communicate with the Eustachian tube and pharynx.

On the other hand, against the first method may be urged the following considerations:

1. A wound involving the whole side of the face, and necessarily leaving a disfiguring scar.

2. Division of the zygoma, with the chance of its necrosis and loss of the coronoid process.

3. Severe bleeding from the pterygoid plexus of veins and perhaps from the internal maxillary artery.

4. Difficulty in finding the foramen ovale (the sphenomaxillary fissure was mistaken for it in Rose's third case), which may be completely hidden by a ridge of bone on the side of the sphenoid bone (the pterygoid spinous ridge).

5. The trephine may readily open the Eustachian tube, and thus render septic infection from the pharynx more likely to occur. In two out of six of Rose's cases this happened, and in one the patient died of septic meningitis.

6. The dura mater may readily be opened—in view of No. 5 a serious complication. The internal carotid artery is also in danger.

7. The ganglion cannot possibly be clearly exposed and removed by this method, and in many cases fragments only have been got away by the unsurgical procedure of scraping the nerve with a scoop.

Necrosis of the zygoma has followed in some cases, and for this reason it would seem
advisable to add to the temporal method a modification proposed by MM. Quenu and Hartmann—namely, division of the zygoma at both ends and removal of the greater wing of the sphenoid, as far inwards as the foramen ovale. This very extensive removal of the whole floor of the middle fossa seems to offer no compensating advantage.

After cutting through the squamous portion as low as the floor of the zygoma, the surgeon may perhaps encroach a little upon the actual base of the skull, but it is quite unnecessary to give a separate name to such a slight modification. Needless complexity has been introduced by attaching a long string of surgeons' names to trifling varieties of skin incisions, or division of additional portion of bone.

Having indicated the belief that the subdural method through the temporal fossa is the only satisfactory way of removing the Gasserian ganglion, some special points of that method deserve notice. It is undoubtedly a difficult and long operation, the difficulty depending on the depth of the ganglion from the surface (at least two inches), the venous oozing, and the degree of firmness of adhesion between the ganglion and the dura mater, forming the so-called cavum Meckelii.

Mr. Horsley finds that it is quite possible to excise the ganglion without dividing the meningeal artery, and this is a real advance in the technique of the operation. However, should it be accidentally wounded and cause troublesome arterial bleeding, the best plan would be to plug the foramen spinosum with a little wedge of bone. As regards the removal of the ganglion itself, there must be no random cutting; the superior and inferior maxillary division must be thoroughly exposed and divided just above the foramina rotundum and ovale, then the root trunk must be made out and severed. Drawing the ganglion outwards will enable the surgeon to deal with the ophthalmic branch without danger to the cavernous sinus, the carotid, or the oculomotor nerves. It is of interest to note that in several of the recorded cases the ophthalmic branch, as in the author's first case, escaped division, yet complete relief to the neuralgia has followed in every one, and of course the nutrition of the eye had not then been endangered. It seems quite impossible to avoid dividing the motor root of the ganglion, and hence the masticatory muscles on that side must atrophy. The resulting inconvenience is less than would be expected.

What is the prognosis or hope of a permanent cure after excision of the Gasserian ganglion? Seeing the disappointing results of neurectomy, removal of Meckel's ganglion, and other operations on branches of the fifth nerve, it is easy to suggest that merely temporary relief will be afforded by the major operation. But at present the testimony is unanimous that where the Gasserian ganglion has been efficiently dealt with the neuralgia does not return. Krause has one case operated on five years ago, and Horsley one over four years, both free from any recurrence.

It is of interest to note that in R. W. Smith's monograph on Neuroma (New Sydenham Society) an illustration will be found showing a large fibrous tumor growing in the Gasserian ganglion.

CASES OF TRAUMATIC MUSCULOESPIRAL PARALYSIS, WITH RESTORATION OF FUNCTION AFTER SECONDARY OPERATION.

Kennedy (British Medical Journal, Nov. 5, 1898) details four cases operated on, three of them successfully. The musculospiral nerve from its close proximity to the bone is one which is peculiarly liable to injury, and its laceration is therefore a not infrequent complication in fractures of the shaft of the humerus. This being the commonest cause of injury to the nerve, it is less surprising that the nerve injury is frequently overlooked at the time of the accident, and the fractured limb having been satisfactorily set in splints the signs of the injury to the nerve are not noticed till the fracture is united and the splints removed, when the results of the injury to the nerve soon become matters for consideration. Thus it is that an opportunity is not often afforded of treating division of this nerve by primary suture, but that the cases are usually seen some considerable time after the accident, when the results of division of the nerve call for a secondary operation.

The interval between the injury to the nerve and the operation undertaken for repair in the three cases which had a successful result was from twelve and a half to fifteen weeks, while in the remaining case eleven months elapsed. In the latter case no improvement whatever resulted from the operation, although as far as the operative procedure was concerned the case had the same course as the others—that is, the ends
of the nerve were brought into apposition, and the wound healed by first intention. The explanation is that the muscles were totally degenerated, and improvement could not therefore result. Sensation in this case was perfect before the operation, and therefore proof of return of conductivity of the nerve could not be obtained. Some improvement in the extension of the fingers, it is true, did result in this case; but this is to be regarded as substituted function from hypertrophy of the lumbricals and intersossi, as extension was effected only at the phalangeal articulations, and not at the metacarpophalangeal nor at the wrist.

Nothing, therefore, can be of more importance in giving a prognosis than the length of interval between the accident and operation, and if this interval is within three or four months recovery may be expected, but if it extends to almost a year recovery of the muscle is unlikely; although where loss of sensation also exists, the recollection of such cases as that reported by Jessop—in which, recovery of sensation took place after an operation performed nine years subsequent to the accident—would lead us to expect recovery of this function at periods very remote from the time of injury.

Any case in which irritability is found in the affected muscles, although only to the continuous current, may be treated with hope of a successful issue; but for the restoration by operation of the conductivity of the nerve, the essential condition is successful asepsis. If suppuration results in the wound, the resulting cicatricial tissue, developing simultaneously with the young nerve fibers at the seat of suture of the nerve, results in compression of the nerve which prevents conductivity and leaves the condition unrelieved. This, no doubt, is the explanation of many failures, especially in experimental work on animals, in which it is not so easy to attain and maintain sepsis.

OPERATIVE REDUCTION OF CONGENITAL DISLOCATION OF THE HIP.

DOYEN (British Medical Journal, Nov. 5, 1898) describes the new methods of reducing congenital dislocation of the hip by operation, which he states give good results up to the age of eighteen to twenty years. The operative technique requires the use of special instruments and may be described in the following steps: (1) The liberation of the head of the femur; (2) reconstruction of the cotyloid cavity; (3) reduction of the head of the femur; (4) closure of the wound and application of fixation apparatus.

1. The head of the femur may be freed in a few minutes by means of a curved incision along the inner border of the tensor fasciae femoris, extending outward and backward below the anterior superior spine of the ilium. The pseudocapsule is incised and resected, and the head and neck of the femur freed from any connection that might interfere with reduction.

2. The acetabulum, obliterated by new-formed osseocartilaginous tissue, is recognized with the index-finger, and to its center and to the required direction there is applied a circular chisel with cutting, curved teeth, which bores a hemispherical cavity. As the tube turns it works its way into the spongy bone, gradually cutting away the latter in thin shavings. The shavings of bone pile themselves up in the interior of the tube. The completion of the formation of the acetabulum is recognized by the resistance of the hard inner surface of the iliac bone. The instrument leaves no osseous debris in the wound, and by turning the tube round in the opposite way the cotyloid cavity may be smoothed and polished.

3. In young children the reduction is effected without much effort. In youth, on the contrary, the strongest efforts may be ineffective. In such a case the patient is placed on a perforated plane, with the pelvis fixed laterally by four to six wooden bolts. The pubes lie against a vertical stem, which is placed between the child's legs, and which turns on its own axis. Above this stem a transverse metallic arm fits into a cylindrical opening. This arm moves from left to right without being able to turn upon its own axis. Above it there fits into an anteroposterior opening an adjusting screw fitted behind with a bolt, and in front with a vertical opening with which a cylindrical stem ends in the form of a spoon. This spoon is attached to the head of the femur or to the great trochanter, and the axis of the instrument, which has its leverage from the pubes, is turned to such an extent that the head is turned directly towards the new cotyloid cavity. The latter is drawn down by turning the screw. As soon as the head reaches the level of the cotyloid cavity, a slight rotation inwards of the spoon turns it at once into the hollow that has been made.

4. The wound is stitched and drained. To facilitate the dressing Doyen has had a spe-
cial support made formed by two steel stems
which fit into the four oval openings in the
metallic rectangle in such a way that the
acute angle they make together may be con-
siderably modified. These stems are joined
at each end by a transverse bar fitted with
pressure screws. At the lower end, towards
the child’s feet, are two supports. The ap-
paratus is arranged according to the child’s
height and the amount of abduction it is de-
sired to produce. The screws are tightened,
and the apparatus becomes really a metal
couch or table of great solidity. The child
is placed on this couch in such a way that the
ends alone of the stems rest on one side on
the operating table, and on some mechanical
support on the other. The plaster bandage
is then applied with ease and freedom, and
without any danger of displacing the head of
the femur. When the plaster has hardened
the two terminal bars are removed, and then
in succession the two stems, etc., behind the
metallic rectangular frame. This simple ap-
paratus is of great value whenever it is
required to apply a plaster-of-Paris jacket
around the trunk or the limbs. With a little
modification it may also be used in the forci-
ble straightening of the spine.

THE TREATMENT OF SPINA BIFIDA BY
“OPEN OPERATION” FOLLOWED
BY CLOSURE OF THE
SPINAL CANAL.

PEARSON (British Medical Journal, Nov.
5, 1898) lays stress on the following points:
(1) The position of the patient should be
lying on the side with the head low. (2) The
first incision should in all cases be a lateral
one, so as to avoid possibility of wounding
cord or nerves. Moreover, this lateral inci-
sion, made on what is the uppermost aspect
of the tumor in the posture recommended,
gives a complete view of the interior of the
sac. Mr. Mayo Robson uses a median inci-
sion in cases of simple meningoecele, but
many authorities state that it is often impos-
sible to say whether the cord is present or
absent; and in any case, as the central por-
tion of the skin and sac will have to be
removed, there is no object attained by a
median incision. (3) It is a distinct advan-
tage to retain the fluid in the sac, or replace
it by irrigation during the separation of the
cord, etc., from the skin. Mr. Robson advo-
cates that in cases where this separation is
difficult a portion of the skin should be left
attached to the cord and placed with it in
the spinal canal. This seems an objection-
able proceeding, and should be avoided if
possible, as covering up such epidermic struc-
tures is likely to give rise to after trouble,
such as the growth of hair or the formation
of sebaceous tumors. (4) The insertion of
the sponge to prevent leakage from the canal
during operation. (5) The liberating lateral
incisions to enable the aponeurotic coverings
to be glided into a position of complete ap-
proximation over the canal, and to be re-
tained there by sutures without the tension
which would otherwise exist. (6) The oper-
ation is applicable to cases of meningomyel-
cele—by far the most common form met
with in practice, and which has usually been
regarded as a form on which it was unjusti-
fiable to operate. (7) The use of a small
drainage tube for a few days between the
dura mater and aponeurotic covering is ad-
visable in case leakage of cerebrospinal fluid
occurs.

THE RESULTS OF OPEN OPERATION IN
THE TREATMENT OF RECENT FRAC-
TURE OF THE PATELLA.

17, 1898), in speaking of the operative tech-
nique, advises a free lateral incision, if the
fragments are to be sutured, since it permits
the more thorough ablation of the joint
cavity, the easier and more perfect coaptation
of the fragments, and the more accurate
insertion of the protective sutures; it also
facilitates operation and diminishes the pos-
sibilities of infection. It is unobjectionable,
since the chances of primary union are quite
as good with a long as with a short incision;
and the superficial cicatrix soon becomes mov-
able, and within a year or two is practically
obliterated. Direct suture of the fragments
insures their firmer contact, and adds to the
strength of union at an early period at a time
when, while comparatively weak, it is yet neces-
sarily subjected to the strain of passive move-
ment. The use of silver wire in place of a soft
suture adds to the strength of union while
still immature, and, if the wire has been passed
through flame at the time of operation, re-
moves the last possibility of deep infection.
If the twisted wire, after having been cut
short, is turned down and thoroughly ham-
ered into the osseous groove of the line of
fracture, and afterward covered in by the
deep sutures, it never requires subsequent
removal; it causes no superficial irritation,
and may be found post mortem after the
laps of years unchanged and incorporated
in the new bone. The deep or protective sutures are essential to the safety of the joint if by any chance the superficial wound becomes infected. The complete removal of blood and clots from the cavity of the joint is important, since, if permitted to remain, blood-clots organize and seriously hamper its future movements, or, at least, greatly increase the labors of the surgeon in their restoration. As the removal of the fibrous tissues and coagula from the osseous surfaces exposed by fracture excites fresh hemorrhage, which continues after the wound is closed, temporary drainage of the joint is of great service.

The secondary or after treatment may be regarded as absolutely essential to the attainment of the best results of the operative method of treatment, and its neglect is responsible for its comparative failures in the hands of some operators. Movement of the joint should be begun early, and the case kept under observation until flexion has been carried beyond ninety degrees, as, left to his own devices, the patient is not unlikely to be content with just sufficient motion for easy locomotion. Lateral movement of the patella should begin at the end of the third week; if neglected, the bone may become fixed to the femoral condyles, and be liable to refracture in the effort at flexion. In both lateral movement and in flexion firm support should be given to the upper and lower borders of the bone. The time required for perfect reestablishment of these movements varies greatly, and is dependent upon the assiduity of the surgeon, the intelligent cooperation of the patient, and accidental conditions presented by the joint itself. In general, it may be estimated at from one to two months after the beginning of flexion. Early neglect, the indifference of the patient, complicating arthritis from concurrent injury of the joint, the retention and organization of the blood-clots, or much inflammatory thickening of the extra-articular tissues, may extend this period. If the case proves obstinate, recovery may be expedited by the use of massage and other manipulation by a skilled masseur, or even by forcible flexion and stretching of adhesions under the influence of an anesthetic. If extensive suppuration has not occurred the function of the joint can always be entirely restored by sufficient and well-directed effort.

The time predicted by Dennis has already arrived when the "final verdict" may be safely rendered. The number of cases which have been subjected to operation is quite sufficient to satisfy the reasonable minds of surgeons that it is neither "an unsafe nor an unjustifiable procedure." There certainly is "evidence," which in 1890 Bull conceived to be wanting, "that the ultimate results have been better than those of non-operative methods." Experience has amply confirmed the logical deductions from positively established premises. The last word may yet remain to be spoken. Operation may be bettered in its details; results may be made more perfect; but nothing can be added to perfect an argument already complete, and no further multiplication of cases can more absolutely demonstrate that which is already irrefragably proved.

**TUBERCULAR LARYNGITIS.**

Fowler (Intercolonial Medical Journal of Australasia, Oct. 20, 1898), together with most laryngologists, believes in the existence of primary tubercular laryngitis. No one has yet seen on the post-mortem table a case of tubercular laryngitis unaccompanied by other tuberculous lesions. The nearest approach is "the case reported by Demme, of a boy who died of tubercular meningitis. The necropsy showed the presence of a laryngeal ulceration, with tubercle bacilli, the thoracic and abdominal organs being at the same time free from tubercular disease." In this case the presence of tubercular meningitis was unfortunate from one point of view, but from another certainly suggestive.

If a case of tubercular laryngitis be examined with the laryngoscope, it is noted that the vocal cord of the side affected is in the cadaveric position—that is, with neither complete adduction nor complete abduction. In other words, the crico-arytenoid joint assumes that natural position of rest that every joint assumes whenever attacked by morbid lesion. The capsular ligament of a crico-arytenoid joint is, in front, thin and loose, but behind is strengthened by a strong posterior crico-arytenoid ligament, behind which again is a firm fascia, connecting and covering the arytenoid muscle, and the crico-arytenoideus posticus. Externally, the capsular ligament is strengthened by the crico-thyroid membrane. Therefore, if the initial mischief be in the joint, one would expect to see the consequent swelling in a front position, between the vocal cords. Thus is explained the interarytenoid thickening observed invariably in every case. The earlier the case.
the greater is the relative prominence of the interarytenoid thickening. Further, it is by no means infrequent to see the interarytenoid thickening, even in early cases, on both sides—not as one uniform swelling, but a swelling that is divided in the middle. This fact shows that the disease has not spread from one side to the other by continuity, but has started in two separate foci, each in the position of a joint. In these cases, both cords are in cadaveric positions, and the voice is more aphonie than it is in a patient with only one side affected.

In fifty autopsies performed the greatest seat of mischief was in the immediate neighborhood of a crico-arytenoid joint, and the joint itself was always implicated. The deepest part of the ulcer, when ulceration existed, was always immediately in front of the joint, and the joint not only communicated with the floor of the ulcer, but was also more or less disorganized. In many cases the arytenoid was a loose piece of dead cartilage. It is not at all an infrequent occurrence for tubercular meningitis to supervene on tubercular joint trouble, whereas the reverse order of affairs has never happened.

It is in consequence of these considerations that, when examining with the laryngoscope a case of tubercular laryngitis, it is always looked upon as a joint disease. Considered as such, there is no difficulty in apportioning to each condition observed its appropriate share in the progress of the disease. Therefore, the interarytenoid thickening, the swelling of the ventricular bands, the ulceration, the swelling over the arytenoid cartilage and in the aryepiglottic fold, and the swelling of the epiglottis, are all extensions of the disease from a joint focus, in an order that one would reasonably expect by virtue of anatomical relationship.

In dealing with the objective signs of tubercular laryngitis perhaps the most characteristic feature noted is the anemic-looking condition of the mucous membrane. The swelling of the ventricular band is always greatest posteriorly. Whatever the degree of swelling attained, the ventricular band, per se, never completely hides the corresponding vocal cord. A small part at least of the latter structure is always visible anteriorly. The swelling over the arytenoid cartilage and the cartilages of Santorini and of Wrisberg assumes a pyriform shape, which is the more pronounced the more the epiglottic fold is involved. In consequence of the quantity of loose areolar tissue, this swelling tends to increase with some rapidity, so that the interior of the larynx becomes more or less obscured; and when both sides are affected the interior of the larynx may be invisible. Swelling of the epiglottis does not always occur. Sometimes the shape is spatulose, with a more or less crenulated margin; at others the swollen epiglottis is bent forwards upon itself. In appearance these swellings are semisolid, as if their causation was due to some gelatinous edema. In reality there is no edema. The tumefaction is entirely due to tubercular infiltration of the adenoid and connective tissues. It is remarkable that the muscles of the larynx, minute as they are, remain unaffected.

The ulceration of tubercular laryngitis partakes of the general pallor, and has the same characteristics as tubercular ulceration elsewhere. In those cases in which the ulceration extends below the vocal cord, it is only as a small tongue-shaped denudation of the mucous membrane, which may be only apparent post mortem. With the laryngoscope only a portion of the ulcer is visible, more or less of it being hidden by the various swellings above it. In appearance it is very different from the punched-out ulcer of syphilis, which is greatly hyperemic, possesses evidence of repair, and may also present cicatricial tissue. Different, too, is the appearance of the cancerous ulcer with its heaped-up, angry-looking margins, devouring without discrimination every structure in its sure and certain advance.

The vocal cord on the affected side, besides being in the cadaveric position, is opaque, with here and there a distended blood-vessel. Later on the cord becomes shaggy. This is due to minute erosions, as if the surface had been gently nibbled by some rodent. The vocal cord on the unaffected side, otherwise healthy, nearly always exhibits isolated swollen blood-vessels, the increased blood-supply being demanded by the extra functional activity called for. The vocal cord is the last structure to be separated from the arytenoid cartilage.

The hoarseness is of an aphonie character. The cause of the aphonie is evidently owing to the inability of the patient to close the rima glottidis, and also to the loss of the resonant qualities of the ventricle of Morgagni, for this chamber is more or less obliterated by the swelling of the ventricular band and by ulceration. Not infrequently the aphonie during a conversation suddenly turns to a falsetto.
In a majority of cases the onset of dysphagia is for fluids only. This is a very characteristic symptom, and exists in no other laryngeal disease. It is explained by faulty closure of the laryngeal lid. When the leak is minute, fluids find their way through sooner than solids. Later on, when swelling and ulceration have increased, there is dysphagia for solids also, and the patient's condition is pitiable.

Sooner or later it becomes necessary to treat this symptom. The spray of a five-, ten-, or even twenty-per-cent solution of cocaine just before meals has now superseded all other forms of anodyne applications. Eventually cocaine fails to relieve the dysphagia, and then it becomes necessary to adopt the following method: The patient lies on his stomach, with his head hanging over the foot of the bed. The food, of a fluid nature, is placed in a receptacle on the floor, and the patient sucks it up through an indiarubber tube. By this method the fluid passes along the roof of the mouth, and so avoids the local lesion.

In great contrast is the pain on phonation in syphilis, and the constant pain of cancer. So insensitive is the diseased part that even irritating local remedies are borne with comparative immunity. In most cases the greatest discomfort is complained of externally by the side of the larynx. It is caused by swollen glands, which, however, never attain any great size, and is relieved by an occasional painting with linimentum iodii.

Barring the dysphagia for fluids, laryngeal patients can, up to a certain stage, take creosote as well as ordinary phthisical individuals. Locally applied, a twenty-per-cent solution of menthol in olive oil is a treatment that was exclusively adopted at the Central London and Throat Hospital as far better than the application of lactic acid or any other drug. The application of the menthol solution causes no discomfort to speak of. Later on it is necessary to cocainize the larynx beforehand; until finally compelled to desist from all active interference. For a time the menthol gives relief. It cleanses the ulcer, and causes a palpable diminution of the various swellings.

Creosote, thymol, pinol, carbolic acid, the oils of eucalyptus and of cinnamon, are all useful in turn, or in any combination. Codeia is the most valuable drug for the formation of a lincture.

The prognosis of secondary tubercular laryngitis is fatal.

**Catheterization of the Ureter.**

Pasteau (Annales des Organes Génito-Urinaire, No. 121, 1898) states that he has performed 140 cystoscopic catheterizations of the ureter, employing therefor the instrument devised by Albarran. He finds neither local nor general anesthesia necessary, and introduces the catheter to the kidney pelvis. Sometimes no liquid will escape through the catheter, either because there is an obstruction, or because the contained fluid is too thick. In no instance was there infection following catheterization, and usually the patients treated were ambulant.

Albarran in the same journal states that he has treated during the last year six patients suffering from a non-febrile unilateral pyelitis, by means of lavage of the pelvis, made practicable by the ureter catheter. First, boric acid was employed, afterwards silver nitrate 1 to 1000. In three cases there was a large quantity of pus, unaccompanied by renal retention. After from five to eleven washings of the kidney pelvis there was remarkable improvement — pains disappearing and the kidney secretion becoming much more clear. Four patients, with a slight attack of pyelitis, were also greatly improved. In the last two cases there was some renal retention, the kidney pelvis containing from four to six drachms of turbid urine. One was cured after pelvic lavage and the operation of hepatopexy. In the second one the retention persisted, but the pus disappeared.

Désnos states that he has seen four cases of high fever consecutive to ureter catheterism, one terminating fatally.

**On the Cause and Mechanical Treatment of Subluxation of the Semilunar Cartilages of the Knee-Joint.**

Shaffer (Annals of Surgery, October, 1898) states that “Hey’s internal derangement of the knee-joint,” occurring as it does both from trivial mishaps as well as from major injuries, and being a not infrequent accident, it seems strange that there should be any doubt as to its essential nature, especially as Hey wrote his description of the trouble so long ago as 1803.

A further study of the subject in Allingham’s treatise, “Internal Derangement of the Knee-Joint,” published in Wood’s Medical and Surgical Monographs in 1890, will dispel all reasonable doubt in the matter. It may be profitable, however, to inquire into its
exact mode of production, but the essential nature of the trouble is well understood.

From these and other sources it may be assumed that the "internal derangement" described by Hey is occasioned by a varying degree of displacement; by even, in many cases, an imperceptible subluxation of one of the semilunar cartilages. In brief, a visible or manually demonstrated existence of the subluxation is not always necessary. The trouble is so far "internal" that in many cases the ordinary physical signs of a dislocation are not to be observed or felt.

Aside from the generally accepted view that this subluxation occurs while the knee is flexed and the leg is rotated, there are other contributive causes which have not been carefully investigated. In short, that it is not the simple fact that rotation of the tibia occurs at the knee during flexion and extension of the joint, for these are normal movements, but rather that there is a delayed or hindered extension and rotation which permits this accident to occur. It would seem that this subluxation is not likely to occur, except perhaps in cases of violent traumatism, while the quadriceps extensor muscle is relaxed.

Nor is the trouble ordinarily considered as one which belongs to orthopedic surgery. Especially since Allingham's time it has been regarded as being within the domain of the general surgeon, and so it is in its purely operative aspects. But, as with chronic diseases of the spine and joints, it has its conservative side, and if orthopedic surgeons can offer relief and cure by mechanical means, the general surgeon will welcome their efforts and aid them in their work.

In order to prevent the recurrence of a subluxation of the semilunar cartilage, it is necessary to correct the undue ligamentous weakness of the joint, and to prevent an abnormal rotation of the tibia—in short, to give the knee and ankle anteroposterior motion only. Under these circumstances undue strain is taken off the quadriceps and the ligamentum patellae, and under favorable conditions the latter, as well as the relaxed crucial ligaments, may shorten very materially in the course of a few months, the object being to prevent every movement at the knee and ankle except anteroposterior motion—in short, to turn the knee into a true hinge-joint, removing entirely the rotation of the tibia. The important part of the apparatus, next to its simple hinge movement, is the joint at the knee, which is so arranged that it will stop the extension just at the point of comfort to the patient, and this point of comfort represents an absence of strain upon the knee-joint ligaments. This is very essential to the cure of the trouble, for experience proves that if the strain is taken from the ligaments they will shorten and the "wabbly" knee will gain stability and strength in a few months.

It is important that the center of the pad at the knee should be opposite the true center of motion (opposite the most prominent point on the internal condyle is near enough) at the knee, and that it should rest snugly against the condyle without undue pressure. The apparatus need not be made heavy, the principal strength being necessary in the rod which connects the knee with the ankle-piece. It is preferable to have this rod on the outside.

1. In many cases of Hey's joint there is an acquired, or perhaps congenital, lateral mobility of the knee-joint. This condition existing, the normal rotation of the tibia in flexion or extension of the knee is greatly increased.

2. In many cases, if not in all cases, there exists an elongated ligamentum patellae, which so modifies the action of the quadriceps extensor muscle upon the tibia that the force of its contraction upon the tibia is modified or delayed in such a way that extension and rotation are not synchronously performed. And it seems more than probable that this condition forms an important factor in the production of the subluxation of the semilunar cartilage.

THE OPERATIVE TREATMENT OF CLEFT PALATE.

EDMUND OWEN (British Medical Journal, Nov. 5, 1898) says that the observations in connection with treatment of cleft palate arrange themselves under three headings: (1) Before the operation; (2) the operation; and (3) after the operation.

The operation not being one of immediate urgency the surgeon can choose his time for it, making such preparations as will, if efficiently carried out, add greatly to prospects of securing a completely successful result.

Thus if a child is brought looking ill or poor, if it is found on inquiry to be liable to severe attacks of diarrhea, or to cough or vomiting, operation must be put off and attention directed towards procuring general and particular improvement of the child. If
When the child is fairly under the anesthetic a strong suture is passed through the tip of the tongue and the latter is pulled out before introducing the gag; in this way it can best be kept from rolling back against the soft palate when the hindmost part of the cleft is being dealt with.

The child is then brought up to the end of the table and the head is allowed to hang back so that the blood may have but slight chance of finding its way into the larynx.

As soon as the edges of the cleft have been denuded, an incision is made along the inner side of the alveolar process, and as this is apt to be followed by a good deal of bleeding, it is well to pause here for a few moments and make firm pressure with a sponge so as to keep bleeding under control. Then the raspatory is introduced and the mucoperiosteal flaps are raised. But, as a rule, they cannot be shifted towards the middle line, and be sutured there without tension, until the alveolar incisions have been prolonged backward into the soft palate. These incisions, which should be quite free, traverse the attachments of the levator and tensor palati, as well as that of the palato-pharyngeus. Then the attachment of the aponessosis of the velum to the posterior border of the hard palate is divided with the curved scissors and the sutures are inserted. For the sutures Owen uses almost entirely silver wire, supplemented in some cases with horsehair. The wire sutures are inserted by a modification of Smith’s needle, which is also made by Weiss. In the case of a complete cleft he inserts about ten or a dozen sutures.

A point of great practical importance is to have lateral incisions made very freely. Indeed, they are made so free that, as the palate is being sutured, they are used for the introduction of small pieces of sponge for removing blood from the front of the nasopharynx, and after operation they together seem to be as wide as was the original cleft; insomuch that onlookers have sometimes asked if there is no fear of the flaps sloughing, or of the incisions failing to be obliterated. In neither of these respects, however, has there been any trouble.

The operation as thus described is extremely simple. It demands the use of no rectangular knives for the separation of the mucoperiostium, and the expansions of the muscles into the soft palate are divided by a simple straight incision. One great point in the operation is to have the edges of the palatine flaps adjusted without any tension.
whatever. The effect of tension after any surgical operation is apt to be disastrous.

Probably the child will vomit when he is "coming around," and if he does this just before he is moved from the table, so much the better. The act of vomiting does not in the least interfere with the line of suturing, though of course if vomiting persists it may be prejudicial. The nurse must be told not to be surprised if fluid ejected from the stomach is blackened by blood which has been swallowed. When the child has been put back to bed his head should be slightly raised on a pillow, with the face turned down, so that the blood-stained saliva may escape from the mouth and fall into some absorbent material.

Whether the mouth spray is used or not a case now and then goes wrong after operation. The child looks ill; the temperature runs up a degree or two; his tongue is coated; breath foul; line of palatine suture becomes swollen and unhealthy; and a thick, stringy, mucopurulent discharge collects about the roof of the mouth. The appearances are ominous and unmistakable. What has happened is that staphylococci have taken possession of damaged tissues, and, undergoing cultivation, are spoiling or completely wrecking the surgeon's handiwork. Owen has at the present time an operation case of this sort in the Hospital for Sick Children. It was in a girl with a complete cleft (and rather a wide one) of the soft, and of the whole of the hard, palate. A thrust cultivation from it on the seventh day showed the gelatin completely liquefied by vigorous staphylococci in less than thirty-six hours.

A fortnight after the original operation, when the sundered and swollen edges of the cleft began to look bright and clean, the child was again put under chloroform, and the marginal granulations having been freshened up, the edges of the flaps were brought together once more and secured by wire sutures, which were inserted quite wide of the cleft. To get the edges together without tension the raspatory was introduced once more by the lateral incisions, and again freely raised the mucoperiosteal flaps. The case has done extremely well, and it seems to promise as good a result as if the edges had adhered by primary union. This, indeed, is the chief point of the paper, and is one of great practical importance.

There is no factor so prejudicial to prompt union after staphylorrhaphy as septic infection, but after a child has undergone this infection we should probably be right in concluding that he could not undergo a second attack; that he has acquired by it a complete immunity, hence a prompt repetition of the attempt to close by sewing should be practiced.

**TREATMENT OF PROSTATIC HYPERTROPHY BY CAUTERHY.**

Nicolich (La France Médicale, Dec. 23, 1898) states that vasectomy is of no service in cases of prostatic enlargement, characterized rather by intravesical projection than by general increase in bulk. When this condition is present and the obstruction is due to a small nodule, cauterization—that is, the Bottini operation—is especially applicable.

Freudenberg a little over a year ago exhibited the case of a man sixty-three years old, who because of absolute retention had been subject to castration by Casper. This operation was absolutely fruitless. The patient was entirely dependent upon catheters and suffered from severe cystitis. Three years later Freudenberg practiced the Bottini operation, making three incisions, one downward an inch in depth, one upon the left lateral lobe, and one about three-fourths of an inch deep upon the anterior lobe. Six hours after operation there was voluntary micturition, and in a month the patient was able to dispense entirely with the catheter. Six months later he was in excellent condition.

Nicolich has practiced the operation upon five cases, all suffering from complete retention. Three were cured, two were improved. The details of but one case are given—that of a man of seventy-four years. The cure seemed to be complete, although retention had been absolute.

---

**BOTTINI’S OPERATION IN THE RADICAL TREATMENT OF HYPERTROPHY OF THE PROSTATE.**

Meyer (Medical Record, Jan. 14, 1899) details his personal experience with Bottini's operation in the radical treatment of hypertrophy of the prostate. He has thus treated twelve cases, and states that his results were as great a surprise to himself as they were a delight to his patients. He counts six cures, two marked improvements, two deaths, independent of the operation; one death with the operation as the remote cause, and one as the immediate cause. The study of the literature of the subject shows that in a series of fifty-seven cases operated upon by Bottini
partly with a cautery, and partly with the incisor, thirty-two were cured; eleven were markedly improved. In his last twenty-three cases operated upon with his improved incisor exclusively, there was scarcely a failure. A tabulation of the reported cases shows that of 164, 80 were cured, 44 were improved, 26 were not improved, and 14 died. Meyer classes as cures:

1. Cases in which patients are able to dispense altogether with the catheter and in which not a drop of residual urine is found after voluntary urination.

2. Cases in which the patients are able to get along without the catheter, but in which some residual urine is still found if the patient is made to urinate without having any desire for it; while when a certain amount of liquid, say 180, 240, or 300 cubic centimeters, is injected into the bladder, it is afterwards passed by the patient to the last drop, and the last few drachms of the injected fluid are squirted out in jerks, as we are wont to see it in perfectly healthy subjects, thus proving that the bladder is being emptied voluntarily to the very last drop.

It has not yet been settled as to the final result of the operation. Bottini states that he never observed a recurrence, and his experience covers over twenty-three years.

Meyer states that after his somewhat extended experience he is ready to advise every patient with non-complicated prostatic enlargement to submit to the galvanocauterous treatment as soon as resort to continued self-catheterization has become imperative.

In patients with very large, soft, and easily bleeding prostate, ligation of the vasa deferentia should precede by two or three weeks Bottini’s operation. This would lessen the danger of a far-reaching thrombosis with consequent pulmonary embolism. The operation should be preceded by cystoscopy, partly to determine the position in which the galvanocauterous knife should be placed, but mainly to detect the possible presence of a quiescent stone.

In regard to the operation it is most essential that the cuts should be made slowly, very slowly; in fact, the wheel of the instrument should be turned as if we had to overcome a tremendous resistance. On the return trip of the heated knife one may first go somewhat faster, slackening up within the last centimeter of the groove in the female part of the instrument, so as to be sure the knife reenters the same. Further, the knife when tested before starting the operation ought to be almost at a white heat, not red-hot as Bottini proposes, who, it must not be forgotten, operates with the bladder empty. But when operating with the bladder filled the platinum knife, surrounded as it is by more or less of the injected water, cannot do efficient work—i.e., burn the tissues thoroughly right and left and in front—unless it be at a white heat. This fact was demonstrated when observing the heated platinum tip of the Paquinil burner when operating, for, instance, upon hemorrhoids with the clamp and cautery. As soon as the red-hot tip is put into action its glow disappears; if at a white heat before, it turns red. Of course, this is due to the immediate loss of heat caused by the destruction of the tissues. If red-hot it will be noticed how very slowly the work is done.

The question as to how many cuts should be made, and at what angle to the median line, is still an open one. The posterior cut in the median line down to the fundus of the bladder is certainly the most important one. The urethral floor must be lowered at its beginning to the floor of the bas-fond. It is obvious that three or four cuts will afford the patient a better chance for thorough urinary drainage than a single one.

The prostate is, of course, thinnest at the upper circumference of the internal urethral orifice; the knife may thus easily cut into the paraprostatic tissue, which carries large veins. Four cuts made at one sitting with the knife at almost white heat, and at angles to be determined by the cystoscope and rectal palpation, will best insure a rapid and successful issue, and thus avoid the necessity of a possible repetition of the operation. The latter would become necessary if after a certain time vesical drainage should not have become perfect as a result of the first interference. The length of the incisions must, of course, vary according to the size of the gland. This question of determining their proper length is one of the most difficult points in the entire operation. Freudenberg’s advice certainly is very good, namely, to introduce the finger into the rectum after the beak has hugged the prostate, and then be guided by the size of the gland in the patient. A middle lobe may at this moment have turned backwards, thus increasing the longitudinal diameter of the gland during the operation. A soft gland can be compressed and will then show a reduced size in the anteroposterior direction. The finger in the rectum will also insure the proper position of the instrument.
within the bladder, before the operation is begun.

If patients are able to empty the bladder soon after the operation, no matter how frequently the calls for urination may come, and if percussion does not show a tympanitic sound immediately above the symphysis as a sure sign there is no retention, absolute non-interference is the best after-treatment. Vesci- cal irrigation does not relieve the patients at all, if they should suffer after the operation. We should by all means abstain from washing the prostatic uretha, to avoid a resulting hemorrhage. Irrigation, no matter how gently it is done, is apt to push or tear off the eschar from the burnt prostate and thus expose the tissue, which bleeds so easily and is so well provided with blood. The elimination of the escharotic tissue should be left to Nature.

The patient may have a call every few minutes, and then be able to void a very few drops only under most intense and painful tenesmus; and this may go on day and night, wearing him out gradually. If in such instances catheterism is difficult and painful, the permanent catheter is indicated. It will bring relief so long as it is retained and not obstructed. If removed too soon after the operation, the former trouble will reappear. We should therefore be prepared to continue the permanent drainage through the urethra for a number of days; if necessary, up to the time of the elimination of the eschar.

The operation certainly is not entirely de-void of danger. This drawback, however, it has in common with all other operations so far devised for this trouble. Its two principal dangers are, first, sepsis or pyemia, and second, embolism of the pulmonary artery or its branches. In the first case streptococci enter the circulation by way of the kidneys or from the proximal pole of a thrombus or thrombi which have formed in the prostatic veins; and in the second, far-reaching thrombosis within the prostatic venous plexuses and within the interior iliac or common iliac vein having occurred, a part of this thrombus by some unfortunate cause is torn loose and thrown into the circulation.

The future must show how these dangers may be reduced to a minimum, or even be entirely averted. At present, it would seem we are justified in stating that the larger the prostate the greater its blood-supply, especially the more enlarged its venous plexuses; the more pronounced the purulent catarrh of the prostatic urethra, as well as of the bladder and even of the pelvis of the kidney, the more dangerous is the operation. In other words, the smaller and less succulent the prostate, the more normal the bladder and upper urin tract, the less is the risk.

Reviews.

A SYSTEMATIC TREATISE OF MATERIA MEDICA AND THERAPEUTICS. By Finley Ellingwood, M.D. With a Condensed Consideration of Pharmacy and Pharmacognosy by Professor J. U. Lloyd, Ph.D.

This book has been written by a professor of materia medica in the Bennett Medical College of Chicago, which as we understand it is an institution usually classed as "eclectic," but the quality of the information which is given in its pages shows that the difference between eclectic therapeutics and the therapeutics of the so-called regular school is no difference at all. Were it not that the author is desirous of placing in the hands of eclectic students a work written by one of their own following, there would be little use in the publication of the volume before us, since the books already upon the market would provide them with facts identical with those which are stated in this volume.

In the preface the author states that he has not only consulted members of his own school of physicians, but that he has also resorted frequently to such books as King's American Dispensatory, the United States and National Dispensatories, and the works of Scudder, Locke, Watkins, Webster, Ringer, Hare, Wood, Bartholow, and Butler. He has also obtained much information from a number of well known medical journals, amongst which we are pleased to note the THERAPEU- TIC GAZETTE.

In an introduction in which general therapeutic considerations are discussed we find the following broad view of medicine stated, namely, that "there are gems of truth scattered throughout the methods of every individual practitioner of whatever creed, and these gems are rapidly becoming common property, so that all feel they have a claim upon them." If the various factions would but unite in this general therapeutic view much of the misunderstanding which leads to the formation of obstructions in the progress of medical science would be avoided. Again, in speaking of the quality of drugs, Dr. Ellingwood states that "he who claims to be a pharmacist, and yet slights the subject of the quality of the drugs, does no credit to pharmacy, and the physician who
belittles this great study is surely ignorant of its intricacies and magnitude." After this preliminary matter we find descriptions of the various preparations like tinctures, emulsions, etc., which are variously prepared by pharmacists, and then the classification of remedies, which is one of the best that we have seen, and which combines a number of the advantages possessed by several of the classifications that are familiar to therapists. In the compilation of the text the author as a rule avoids quoting writers in any school of medicine, and for this reason it seems to us that the value of the book is increased, in that the views expressed are largely his own, and the reader is not at a loss to know what the views are which are held by the author. Almost without exception the therapeutic directions given as to the use of remedies are in accord with prevalent teaching by the best therapists in the regular profession, and while at times it seems to us as if the author is optimistic in the views which he holds concerning the efficacy of certain remedies, this optimism is at no time excessive and is perhaps wise, in that it antagonizes the tendency to therapeutic nihilism which seems to crop up now and again in medical literature.

The weakest point of the book seems to us to be that part which is devoted to medical electricity, which is so short as to be almost useless. While the volume covers 700 pages, it is not to be considered an exhaustive treatise upon pharmacology and therapeutics, but rather a concisely written compilation of the modern use of drugs, although it is notable that a number of remedies which we are accustomed to prescribe with considerable frequency are not thoroughly considered. In the next edition we think it would be wise if the author would introduce information concerning the poisonous and untoward effects which the more powerful drugs often produce.

If all the readers of this work will become as good therapists as its teachings are qualified to make them they will do well.

Ocular Therapeutics for Physicians and Students. By F. W. Max Ohlemann, M.D. Translated and Edited by Charles A. Oliver, A.M., M.D. Price, $1.50.

This is a small octavo volume of a little over 250 pages, printed on good paper and in large type, and detailing the various therapeutic measures other than operative procedures which are useful in the treatment of abnormal conditions in the eye and adjacent parts.

The German edition is dedicated to Schweigger of Berlin, and the American translation to Dr. Wm. F. Norris of Philadelphia. The actual translation is made by Dr. David Riesmann.

As is indicated by the title of the volume, it contains a very large number of formulæ, indicating how various ointments, lotions, and other medicinal preparations can be used in the eye. The editor has, in foot-notes, given the synonym in the United States Pharmacopoeia of the various preparations mentioned in the prescriptions from the German Pharmacopoeia. This book ought to prove exceedingly popular to the general practitioner, who is often at a loss to know how to treat inflammations and other conditions of the eye which do not require correction by means of lenses or operative procedures.

This, the seventeenth, volume of this well known encyclopedic work has just appeared, prior to the issue of Volume XVI, which we are told has been unavoidably delayed. It deals with certain of the infectious diseases and malignant new growths, and opens with an article by William Hallock Park, of New York, on diphtheria, in which he discusses this disease from its bacteriological, pathological, and diagnostic standpoints. As is well known, Dr. Park has had ample experience to justify his authorship of such an article. His pages are followed by those of Dr. Abraham Jacobi, who discusses the symptomatology and treatment of this affection, and it is needless to say that he is in favor of the antitoxin method. He also takes an opportunity to hold up to scorn the attempt of Behring to patent his antitoxin abroad and in this country. Following this article by Dr. Jacobi, which is characterized by his strong personality and the positive statement of his views, is one by Victor Babes on tetanus. We note with interest in the part devoted to treatment that, after discussing the various drugs which have been employed with more or less success, he says, under the heading of "Specific Treatment," that it has not been found possible to reduce the mortality of tetanus by the use of antitoxic serum to anything like the extent which was prophesied by Behring, and while he believes he
has used this remedy more largely than any other person, he has been unable to save animals even with very large doses, unless the infection has been of such a character as to be favorable to the patient. It is interesting to note in view of the cases which have been recently published, in which the tetanus antitoxin was injected directly into the brain, that in his opinion the nearer it is injected into the brain and threatened nerve cells the more assured is the probability that it will be able to prevent the toxin from attacking these parts.

The next article is on the general pathology of cancer, by W. Roger Williams, of Bristol, England, in which he gives a historical and pathological survey of this condition in an exhaustive article of many pages, and forming the largest part of the volume. Following this is another one upon the symptomatology and treatment of cancer, by William B. Coley, of New York, which is illustrated and is also exhaustive. This article is again followed by one on sarcoma, by Dr. Williams, which is in turn followed by one on the symptomatology and treatment of these growths, by Dr. Coley.

The volume concludes with articles upon malignant new growths of the skin, by Dr. John T. Bowen of Boston, and another by Edward McGuire of Richmond, Va., upon malignant diseases of the female organs of generation.

Volume XVII is certainly as good as its predecessors, and in some respects is distinctly superior.

This is a little book of less than 150 pages, detailing the system of mechanotherapy as practiced by the Royal Gymnastic Central Institute of Stockholm, Sweden, and quoting from the various well known authors upon massage and Swedish movements. The illustrations, which are pen-and-ink sketches by the author, are rather crude as compared to most illustrations found in books at the present time, but they serve to illustrate their purpose. As few members of the profession are desirous of investing in large, expensive manuals dealing with this subject, and as this one gives adequate description of the various motions and exercises, it can be commended to those who wish a brief description of these valuable methods of improving the general health. The price of the book is $1.

The author tells us in his preface that in this small volume will be found the essentials for chemical diagnosis and a description of all those chemical processes most useful to the practicing physician. It is made up of the last eighty-eight pages of his "Text-book of Medical and Pharmaceutical Chemistry," with an additional chapter upon Urinary Diagnosis.

We have already referred in terms of warm praise to Dr. Bartley's larger volume, which we have just mentioned, and this little manual possesses all the good qualities of the larger one, save of course that it is very much more limited in its scope. We do not remember having seen so condensed and yet so complete a manual of clinical chemistry for so small a price, the book being sold for $1. We can cordially recommend it to students and practitioners who are careful enough in their work to make chemical analyses.

This work, born of a book on the Treatment of Wounds, published by Pilcher in 1883, differs so greatly from its predecessor that it can in no sense be considered a second edition of that, in its day, most popular and valuable brochure. The first few chapters are devoted to general principles, including the constitutional effects of wounds, their repair, and the sequelæ and complications incident to them. The relation of microorganisms to wound disturbances is given a chapter to itself; while antiseptics, antisepsis, and antiseptics are subjects considered in the last portion of the first section of the book.

The second section is devoted to the practice of wound treatment, and naturally it opens with an extremely practical chapter upon the prevention of infection.

It would have been well had Pilcher used the weight of his authority in popularizing the use of gloves during operation; though the manner of using them and the advantages incident to their use are mentioned, there is nothing said which would lead the reader to believe that the author of this book is convinced of their utility.

In the treatment of hemorrhage, the technique of hypodermoclysis is admirably de-
scribed. Further chapters of this section are devoted to cleansing of the wounds, apposition of the wound surfaces, protection against disturbances of healing, and the relief of complications.

In the treatment of systemic conditions the modern serum-therapy is not noted, probably because the author believes the value of this method still remains to be proven.

The second part of the book is devoted to special wounds. The second chapter of the first section in this part, dealing with gunshot wounds, is particularly to be commended. Throughout the work modern teaching and modern methods are freely set forth. The book should be useful to both surgeons and students, and should receive, if possible, even a more cordial reception than that accorded its predecessor fifteen years ago.

It is not necessary to do anything more than announce the appearance of the third volume of the second series of this monumental work, which has been the subject of admiration by literary and medical men all over the world, and which has aided medical practice and medical literature to an untold extent. However much we may be inclined to rail at the political misdeeds of our lawgivers, the publication of such volumes as these makes us recognize the fact that some of the money at least is very well spent. We congratulate Dr. Merrill, the officer in charge of the library, upon the completion of this volume.

It is not surprising that the students of the Philadelphia Polyclinic listened with much interest to the lectures upon which this book is founded. It is admirable in every respect, and puts before the student the difficult subject of the muscular anomalies of the eye in the most acceptable manner. Indeed, it is not altogether elementary, and every practitioner of ophthalmology will do well to read and digest this manual, which begins with a brief description of the anatomy and physiology of the ocular muscles, then takes up the structural anomalies or the ocular palsies, and goes on to a consideration of heterophoria—that is, insufficiency of the ocular muscles—and heterotropia, or the various forms of squint, and concludes with a brief chapter descriptive of the operations of tenotomy and advancement.

In the chapter on general diagnosis all of the well known tests are described, and Landoit’s method of determining the amplitude of convergence especially commended, which, indeed, is believed to be the best test of the real power of convergence. Certainly the authors are entirely correct in stating that the primary prism-convergence found at the first examination in most eyes will not exceed twenty degrees, and that the ratio between adduction or prism-convergence, and abduction or prism-divergence, cannot be accurately stated. As the authors express it, there is no arbitrary standard.

There are one or two sentences in this book that ought to be impressed on students and (with deference) on some practicing ophthalmic surgeons, as golden rules never to be broken, viz.: “In all cases (of esophoria) the estimation of any optical defect under complete paralysis of accommodation, and the wearing, for some weeks, of as nearly a full correction as can be borne with comfort, are essential. No other treatment directed to the restoration of the lost equilibrium should be inaugurated until glasses correcting the ametropia have been worn sufficiently long to remove any pernicious influence born of constantly overtaxed accommodation. The experience of all ophthalmologists confirms this statement, and no surgeon of judgment or ability will apply treatment directly to the muscles until he has given the patient the opportunity to cure himself by wearing glasses.” Again, referring to the treatment of exophoria: “In no case is prism or operative treatment to be advocated unless the indications are significant.” Again: “In all cases (of esophoria) operation should be reserved as the final means of effecting cure.” But the authors are not adverse to operative interference entirely, for they believe, “after all other means have been faithfully tried and failed, esophoria of more than ten degrees will almost invariably demand surgical interference.” It is the reviewer’s experience that, a few cases excepted, esophoria can be managed without surgical interference.

In esophoria the authors prefer tenotomy divided between the two recti, but in exophoria they agree with Landoit that tenotomy
is not an advisable operation, which in their practice has fallen almost into disuse. They prefer advancement or shortening, but admit that their results have not always been satisfactory, and think that many failures to cure exophoria are due, as Stevens long ago pointed out, to abnormal vertical deviations. Very properly the authors are warm advocates of prism exercise. Space does not permit further quotation from this exceedingly interesting and valuable manual. As it has given the reviewer great pleasure to read it, it gives him still greater pleasure to heartily recommend it to all students of ophthalmology.

G. E. DE S.

**Correspondence.**

**LONDON LETTER.**

**BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P. LOND.**

One of the most interesting items of medical literature in the current month has been the communication of Mr. Clement Lucas to the Royal Medical and Chirurgical Society on “Gonococcus Joint Disease in Infants Secondary to Purulent Ophthalmia.” It will be remembered by many that as long ago as 1885 Mr. Lucas drew attention to this association of disease in three cases published in the British Medical Journal. At that period the pathology of gonorrhea and the incident complications was a matter of speculation, as it was not till 1885 that Bummb showed the pathogenetic relation of the gonococcus to the urethral discharge. In 1885 Lucas wrote: “I am not aware that any connection between ophthalmia neonatorum and synovitis has ever been observed or described; but there seems no just reason if, as is generally supposed, the synovitis of gonorrhea is the result of absorption of morbid products from the urethral mucous membrane, why the conjunctival membrane should not offer an equally favorable absorbing surface.” Fourteen years later Mr. Lucas is able to tabulate from all sources no less than twenty-three cases in which the association has been established beyond all doubt, and moreover is able to render the vague theory of “absorption of morbid products” in terms of modern pathology as “the entrance of the gonococci through the conjunctival mucus membrane to the lymphatics or blood.” This further series of cases serves to confirm clinically Mr. Lucas’ prediction that there would be shown to exist two forms of joint disease in
infants of the nature of ophthalmial rheumatism: (1) a very acute arthritis, accompanied with much swelling, tenderness, and redness, strongly suggesting a tendency to suppuration; (2) a subacute synovitis, giving rise to a good deal of effusion and pain on movement, but to little or no superficial redness.

Mr. Lucas draws several important conclusions from his new series of cases. As to the origin of the ophthalmia, in eighteen cases it was due to gonorrheal infection from the vagina during labor, while in five cases it appeared at a later period. Again, the time after the initial infection at which the joint disease may be expected to show itself is estimated as the end of the second week or the course of the third. Although almost all the joints are liable to be affected, there is a very marked predilection for the knees, and particularly the left knee. Mr. Lucas declines to assign to chance the frequent affection of the left knee, but advances an elaborate theory to explain it. He points out that mothers and nurses usually by preference carry their infant on the left arm so as to have their own right arm more free for use; in this way the right knee of the child is protected by the nurse’s body, while the left knee is more exposed to injury. If this lowering of resistance by injury does actually make the left knee more susceptible to gonococcus infection, the same should be true of every other infective arthritis of infants. We doubt if this would be found statistically to be true of tubercular disease. With regard to the course and duration of the inflammation, the course of the joint disease bears, as one would expect, a definite relation to the course of the disease at the infecting source; and this in turn is largely dependent on the early and active adoption of appropriate treatment. Some cases will then recover in from ten to fourteen days, but the majority run a course of from three to five weeks before complete resolution takes place. Complete resolution is almost invariable, and as a rule with perfect mobility of the joint, even when the inflammation has advanced to the verge of suppuration. Suppuration may occur in the joint, but here in all probability we have to do with a mixed infection; in two of the three cases recorded in which suppuration occurred, the gonococcus was found in the ophthalmial discharge along with streptococci or staphylococci.

In the matter of treatment Mr. Lucas concludes that it should be directed to the early and complete cure of the purulent ophthalmia which is the source of infection; as soon as this has been cured by frequent applications of antiseptic lotions, the joint troubles will subside. Locally he uses evaporating lotions to reduce the surface heat, or wrappings of wool, lightly covered with a bandage, to protect the joint from injury. In older infants it is well to fix the knee so as to insure more perfect rest, but in younger infants this for obvious reasons is inapplicable. Every one will agree with Mr. Lucas in deprecating the use of the aspirator.

Dr. Ashley gives a timely warning of the dangers of chlorate of potassium in the treatment of disease in the Edinburgh Medical Journal. These remarks are an appropriate sequel to the reduction of the dose in the new Pharmacopoeia from 10–20 grains to 5–15 grains. The salt is an invariable member of the domestic armory, and so far as our own experience goes the only recognized limitation of dose is the amount that can be conveniently dissolved in the mouth in the form of lozenges in the course of twenty-four hours. Dr. Ashley condemns the drug as practically useless in simple acute tonsilitis, and in the specific tonsilitis of scarlet fever and diphtheria. With regard to the two latter diseases this is undoubtedly the case, but we fancy that with regard to acute tonsilitis he would find himself in a minority of opinion. It often seems to act like a charm, given either internally or taken locally, but if persisted in for more than a short time it has often seemed to us to serve to keep up the irritation. For ulcerative stomatitis Dr. Ashley gives three to five-grain doses to a child of three to seven years every four or six hours, so that the daily dose amounts to about twenty grains. He prefers to give the dose by the stomach rather than apply it locally, as the local effect appears to be greater when the salt is given off in the saliva than when applied directly to the ulcer. Dr. Ashley records a case of alarming toxic symptoms in a child of fourteen months from fifteen grains per diem. Short of such serious symptoms, chlorate of potassium is a not infrequent cause of chronic anemia in children with severe depression and enlargement of the spleen.

The British public is slowly awaking to the fact that it is nursing in its bosom a serpent—or rather a multitude of serpents—in the form of the “conscientious objector” to vaccination. Unofficial statistics seem to show that in the closing four months of the
past year the plea was allowed in the case of no less than a quarter of a million infants. Probably, however, this cannot be accepted as an average number for similar periods, as no doubt the objection was registered in many instances on behalf of children of riper years, who had previously defied the law. When we find that in one town no less than 27,000 children were thus exempted, the magnitude of the danger may be readily appreciated. The recent epidemic in Gloucester has shown what mortality may be expected in these days of rapid communication and traveling, of compulsory school attendance, and of congregating centers for worship, for music, for social intercourse, multiplied a hundredfold beyond the number of Jenner's time. Mrs. Garrett Anderson, in a vigorous letter to the Times of January 10, exposes the logical absurdity of "isolation" as a substitute for vaccination. If nobody be vaccinated, the only possible form of isolation is banishment to some desert spot, the reaching of which in a civilized country must defeat the very object for which isolation is sought. The presence of a medical man or a nurse alike would violate the practice of isolation, as not being protected by vaccination, they will be susceptible to infection. The great question is how to deal with this evil. Some concerted action on the part of all who themselves have been vaccinated might do much to check the spread of the evil. It has been suggested that no one should be employed either in domestic service, in trade, or in any public office who has not been vaccinated. We fancy that such a patent interference with the liberty of the subject will hardly commend itself to Englishmen. The fact is that the only solution of the dangerous situation created by the mischievous legislation of the present Government lies in a repeal of the existing law. Alas! the measure has the imprimatur of Lister. And this is the testimonial of the father of bacteriology to the memory of Jenner.

Mr. Chetwood-Aiken calls the attention of the profession to the advantages possessed by bromohydrate of arecoline as a mystic. The drug does not seem to have received the clinical notice it deserves, either in this country or abroad. Arecoline is one of the alkaloids of areca nut, the seed of Areca Catechu, and the bromohydrate is a white crystalline soluble salt. "Its physiological action is closely allied to those of pilocarpine and pelletierine. Taken internally it causes vomiting and diarrhea, and it is in addition a sialagogue, diaphoretic, and vermifuge." The solution employed in ophthalmic practice is a half-per-cent aqueous solution, and its first application causes a tingling sensation, which passes off in two or three minutes, when myosis commences. Full myosis is obtained in from ten to twelve minutes and is accompanied by spasm of the ciliary muscle; this ciliary spasm may appear prior to any signs of myosis, or not until the pupil is fully contracted. Full contraction lasts for about half an hour, and then lessens, so that the eye regains its normal state in from one to one and a half hours. When the eye is healthy its tension is very little, if at all, decreased by it, while in glaucoma it is much superior to eserine. There are none of the unpleasant after-effects of eserine. It is more rapid and more powerful than eserine, but its effect is less enduring. It is more potent than eserine in antagonizing the mydriasis of homatropine. Its aqueous solution does not undergo decomposition even after prolonged keeping.

Dr. Calvert at the Royal Medical and Chirurgical Society, in a lucid paper, exposed one of the fallacies that are handed down from textbook to textbook to the embarrassment of students, viz., that aortic aneurism is in itself a cause of hypertrophy of the left ventricle. The statistics of post-mortem examinations at St. Bartholomew's Hospital showed that in 124 cases of aneurism of the arch of the aorta, in sixty-eight there was no hypertrophy of the left ventricle; in forty-seven cases the hypertrophy was referable to other causes that were present; while in the remaining nine cases the hypertrophy could not be shown to be due to the aneurism to the exclusion of other causes present. A priori one would hardly expect aneurism to cause hypertrophy, seeing that it increases the vascular area. Dr. Morrison suggested that the important feature in the production of hypertrophy of the left ventricle was leakage through the aortic valves.

In a recent letter we referred to the remarkable influence of a large dose of sulphonal on a case of delirium tremens. Now Dr. Mortimer has been recommending the Chelsea Clinical Society to treat their cases of delirium tremens by inhalation of chloroform. The immediate result of the inhalation in Dr. Mortimer's case was six hours' continuous sleep, followed after an interval (during which the patient was quiet) by sleep lasting nearly the whole of the following day and night, accompanied by rapid recovery in all respects. It seems that a similar course
of treatment has been recorded in a few other cases with benefit, and with none of the ill effects liable to follow on administration of anaesthetics to alcoholic subjects. Since attention has been called to the toxicity of sulphonial several cases have been recorded in various parts of the country. One of the latest is a case of acute poisoning, only just escaping a fatal termination, brought on by 35 grains of sulphonial in divided doses of 20 and 15 grains at an interval of twenty-four hours. This is, of course, an instance of special idiosyncrasy to the drug, but we think it should be noted that the patient had been taking bromide of potassium, and it is a question how far the activity of the sulphonial was enhanced by the previous bromide treatment. Unfortunately it is the public, who have taken the administration of sulphonial into their own hands, that need the warning, more than the medical profession.

---

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Dr. Brocq, physician of the Paris hospitals, and specialist in skin diseases, has tried yeast in the treatment of furunculosis, and has found it most efficacious. This treatment had been already mentioned by Follin in his treatise on surgery, as well as by Gingnet in his work on "Rational Treatment of Furunculosis," and they had based their appreciation of this medicinal agent on what had been mentioned in a letter written by Dr. Mosse to the English Lancet. Dr. Debouzy, of Wignelies (Nord), had also spoken of this drug. Dr. Brocq began trying it in 1894, and has used it on about fifty patients suffering from diverse complaints, such as carbuncle, boils, and infectious or inflammatory affections of the skin.

Dr. Brocq has long been subject to periodical attacks of carbuncle, occurring every four or five months, and replacing former attacks of asthma. From 1894 to 1895 he tried colchicum, a drug which he had recommended, but this substance produced gastric trouble, so he decided to see how yeast would act in his case. Its effects have been most curious and apparent, and Dr. Brocq, in a recent article on the subject, has described at great length how the pains diminished rapidly after the third day, all edema and inflammation being checked in their progress, and in some cases suppuration being warded off. Dr. Brocq has described several other cases where surprising results were obtained most rapidly, and there was no recurrence of the disorder. He uses fresh beer yeast. When this substance is bought from the Paris brewers it seems to be a sort of light chestnut-colored cream, and is uniform in appearance, but on being allowed to stand three distinct layers are formed. The latter should be well mixed together, and a heaping teaspoonful taken at each meal in a glass of water or beer. Bakers' yeast can be also ordered, but it is not so efficacious. A piece about as large as a small hazelnut may be mixed with honey, as Dr. de Backer recommends, and this quantity is to be taken thrice daily at each meal. The full dose is on an average three teaspoonfuls daily, but it may be increased to nine or ten in some cases. The administration of this drug may cause indigestion, and in some rare cases diarrhea. These symptoms are not very tenacious, and by using this medication discreetly no untoward results need be expected. Dr. Brocq has not found it necessary in most cases to use complicated external applications. As to the yeast, it should be quite fresh, and changed every day in summer and every two days in midwinter.

Dr. Plicque, one of the most distinguished among the younger generation of Paris physicians preparing for the examinations that entitle them to the position of physician of the hospitals, has recently written an essay on the treatment of Addison's disease. According to the author, we are at the present time better prepared to fight this disease, and this is due not only to the progress made in opotherapy, but also to a clearer knowledge of the pathogenesis of this affection and a more rational treatment of its principal symptoms—asthenia, pains, and gastrointestinal symptoms. Opotherapy is, of course, the keystone of any treatment whatsoever, as being specific and clearly useful. But beside this there is what one may call the symptomatic treatment of the different symptoms, and we shall begin by studying the asthenic condition, so predominant in this malady. This latter condition would seem to be due to an autointoxication by the toxins produced by the action of the muscles which are no longer destroyed by the suprarenal capsules. It is therefore indicated to recommend avoiding all physical work or muscular exertion, or at least to reduce it to a minimum. When this can be obtained, combined with a sojourn in the country with a favorable climate thrown
in, very appreciable results can be reasonably expected. Great care should be taken to avoid any sudden fatigue, which is apt to destroy all the good effects obtained previously. The physician should give minute directions as to diet. The latter should be abundant and nourishing, but there is one point to be observed: the kidneys are often at fault and there is danger of autointoxication. Certain gastric troubles, such as loss of appetite, vomiting, diarrhea, are due to renal insufficiency. In such cases a milk diet is beneficial; but it should not be continued too long, and as soon as possible the yolk of eggs, finely mashed vegetables, white meats, and very fresh fish should be added. Raw meat should be employed only when easily assimilated. Meat powders, when quite fresh, are palatable and very nutritious. As for oysters, shell-fish, brains, marrow, cod-liver oil, butter, and other fatty foods, they are to be employed according to the patient's taste.

A certain number of drugs will be found useful. Oxygen is indicated when there is vomiting and gastric trouble. Sulphur baths, rubbing of the skin, and massage give good results, but hydrotherapy on the other hand is absolutely contraindicated. Electricity has been highly spoken of by Jaccoud and SEMMOLA. The static bath administered with sparks on the painful regions has proved effective, as in all such cases; faradization of the muscles could only prove a source of fatigue. When there is gastric intolerance, galvanization of the pneumogastric nerves is sometimes successful when vomiting is incessant. Strychnine and arsenic are good tonics to be used in such cases, but ought to be given in moderate doses with periods of rest. Dr. Robin has used injections of glycerophosphate of calcium (20 centigrammes only), and has obtained thereby a steady amelioration. Glycerin, which has been much praised by Greenhow, should be given in moderate doses of forty grammes, for instance, ten grammes of brandy or rum being added to cover the taste. Iron, quinine, kola, or coca can also be employed. The attacks of pain, which are sometimes very sharp, may be relieved by external methods, such as massage, electrization, spraying with chloride of methyl, or by the exhibition of drugs, such as antipyrin or salicylate of sodium. These are preferable to morphine, to the use of which may be perhaps attributed certain cases of sudden death by rapid uremia. Syphilis at times produces in women some of the symptoms of Addison's disease, and in such cases a specific treatment is indicated, but if no appreciable result is produced immediately, this treatment should not be continued, as it has a most pernicious influence upon the disease. Suprenale opotherapy, though sometimes without effect in cases attended by advanced cachexia, has given good results in the hands of Béclère, Marie, and Dieulafoy.

Subcutaneous injections must be employed with precaution. D'Arsonval gives the following formula:

Suprenale capsules, 10 grammes;
Glycerin at 30°, 10 grammes.

The capsules are chopped up fine and put into glycerin. Five grammes of sterilized solution of salt water, 25:1000, must be added. Sterilization can be obtained by means of carbonic acid under pressure after filtration, and of the solution thus obtained two centigrammes can be injected daily, diluted in equal parts of boiled water. When given by the mouth capsules containing ten centigrammes of suprenal capsular substance are to be administered, two to four each day; or the fresh substance may be employed.

It is sometimes difficult to arrest palpitation in chlorosis or anemia. Iron, cardiac tonics, and digitalis are useless, and sometimes injurious. A point which has been often enough overlooked, says Dr. Milhiet, of Paris, is the vascular spasm and consequent arterial hypertension. The symptoms observed in such cases are cold in the extremities, alternate paleness and coloration of the face, and emission of light-colored urine. To remedy this condition massage and cold douches may prove beneficial. Dr. Huchard recommends the following liniment:

- Alcoholic extract of juniper, 120 grammes;
- Alcoholic extract of lavender, 60 grammes;
- Essence of turpentine, 30 grammes;
- Menthol,
- Thymol, of each 0.50 centigramme.

Vasodilatory remedies should be employed. Trinitrine may be given in doses of six to ten drops daily (alcoholic solution one-percent); or one may use tetranitrol or tetranitrate of erythrol, a new vasodilatory agent tried by Bradbury and Broadbent in England. Its action is slower, but more lasting, than that of trinitrine. Its effects are noticeable only fifty minutes after ingestion, but last five to six hours. The maximum dose of tetranitrol is 0.03 to 0.05 centigramme for one dose, given in an alcoholic solution.
Our readers may be interested to know what are the latest results of Drs. Roux and Borrel's treatment for tetanus. In a thesis published on this subject by Dr. Delvincourt and analyzed in the last number of the Journal of Therapeutics by Dr. Sainton, house physician of Professor Debove, two cases followed by recovery are cited. An active intervention is necessary. In one case the operation took place thirty-two hours after the initial symptoms of masticatory trouble, and eight hours after trismus had set in; and in the second case six hours afterwards. Uterine tetanus seems to be as fatal as ever, as the five cases cited so far were followed by death.

ROME LETTER.

By John L. Eyre, M.D.

Early in 1898 the Italian Society for the Study of Malaria was established in Rome, largely through the exertions of Dr. Celli, the professor of hygiene in the University of Rome, and whose name is so well known in connection with that of Marchiafava and other Roman scientists in relation to their researches in the plasmodium malariae. The funds provided by this Society have enabled Professor Celli, Professor Grassi, and several other Italian scientists to study malaria in its various phases during the past summer in the most desolate parts of the Roman Campagna. Their discoveries have been summarized by Celli in an interesting report which he read at the first annual meeting of the Society lately held in the Institute of Hygiene of Rome. As this report contains an account of several important researches on malarial fevers I give a translation of it almost in full as my first contribution to the Therapeutic Gazette.

Professor Celli began by stating that the report embodied the results of the investigations on malaria made by members of the Society during the past season of fevers—that is, from the beginning of July till the date of the meeting (Dec. 3, 1898). It was known that in recent years the life of the malarial parasites in the blood of man and of animals had been well recognized. Notwithstanding this, two problems of enormous interest for humanity had remained enveloped in darkness—namely, how the malarial germs live in the environment, and how from the environment they return to infect man and the lower animals. When these problems are solved one may hope to find the mode either of killing the maleficient germs where they lodge, by means of direct drainage, or of protecting man and the useful animals from them.

But may not this latter scope of preservation, the supreme end of all our studies, also be reached by another way—that is, by means of substances which give artificially that immunity which Nature sometimes concedes both to man and the lower animals? In reference to the first problem it must, above all, be remembered that the Mexican authors Smith and Kilborne have demonstrated, and Koch has confirmed, that certain ticks are undoubtedly the vehicle of bovine malaria.

As to the vehicles of human malaria, in the Institute of Hygiene at Rome the numerous and repeated attempts to reproduce malaria in birds by the inoculation both of malarial earths and of cultures of ameba which there are found were always fruitless, and water as a vehicle of malaria was also excluded, which has been abundantly confirmed elsewhere. On the other hand, some authors had already thought that mosquitoes were in some way connected with the biology of the malarial parasites. Thus, Laveran and Manson had maintained that man is infected by drinking water contaminated by mosquitoes, in which, after the puncture and the sucking of the malarial blood, the infective parasites are developed as an intermediate host.

Bignani, on the other hand, by the process of exclusion and with indirect proofs, came to the conclusion that malaria bears itself in respect to man as if it were inoculated by mosquitoes, and Bignani and Dionisi have also, since 1894, endeavored directly to prove this; but through want of means they have been unable to continue their researches; and in the past year only has Dionisi been able to initiate some experiments which were favorable to the hypothesis of inoculation.

Meanwhile, under the wise guidance of Manson, Ross of Calcutta succeeded in determining the cycle of life of the malarial parasites of birds in the body of a particular species of mosquito.

The direct proof of the possibility of transmission of human malaria by these insects was then more than ever urgent; and fortunately it was also possible, thanks to the means that the Society from its initiation has been able to obtain.

The members were able to institute ex
periments in two modes: that is, to investi-
gate how malaria acted in relation to a cer-
tain number of men living in a highly
malarious place, and protected in an absolute
way from the bites of insects; and to inves-
tigate if individuals never subject to malarial
fevers, living in a healthy place and bitten
by mosquitoes captured in malarious places,
would catch the fever.

The first mode was attempted by Fermi in
the Pontine marshes, but many difficulties
were met with in carrying out the experi-
ments in a rigorous way. The second was
therefore adopted. In a room of the Ospe-
dale S. Spirito individuals were put to sleep
who had resided for some years in the hos-
pital, and who never had had malarial fevers.
In this room adult mosquitoes brought from
malarious places or developed from larvae col-
lected in the Campagna were set free.

Thus four experiments were made from
the end of July onwards. The first, in two
individuals with adult mosquitoes captured
in Porto, was interrupted after a few days for
want of sufficient material. The second, in
one man only, with mosquitoes developed
from a collection of larvae, was continued
from August 8 to 28, and was interrupted
when the patient had a slight rise of tem-
perature with a sensation of chill and malaise,
which ceased without further consequences.
The third, in a man named Sola, was con-
ducted in the same mode from August 24 to
September 19, being interrupted when Sola
began to suffer from malaise and headache,
with a slight rise of temperature. In Sola
also this remained without result. Analo-
gous experiments, and with similar negative
results, were made by Fermi at Terracina
and by Grassi at Rovellasea.

Meanwhile, starting from the considera-
tion that if mosquitoes truly inoculate the malarial
parasites in the localities where malaria
develops, there are several species to be
found, Grassi undertook a series of compara-
tive researches in the most varied parts of
Italy during the past estivo-autumnal season.
He came to the conclusion that in the ma-
larious places several species of mosquitoes,
large and small, exist in abundance which do
not find the suitable conditions for reproduc-
tion in non-malarious places. Taking into
consideration the abundance of the above
mentioned species in the season of fevers,
Grassi came to the conclusion that three
species must be held to be extremely sus-
picious. They are: the Anopheles claviger,
the Culex penicillaris, and the Culex malariae.

To the puncture of these three species,
captured in Maccarese, that same Sola, in
vain bitten by other mosquitoes, was sub-
jected by Bignami, in association with Grassi.
This experiment lasted from September 28 to
October 21. On November 1 Sola was seized
with grave malarial fever, of which he was
perfectly cured by means of quinine; in his
blood were found parasites of the estivo-
autumnal species.

The attendant of the laboratory of com-
parative anatomy, who went to capture the
three above mentioned species of mosqui-
toes, and which he captured as they hit him,
was meanwhile also infected with estivo-
autumnal fever.

Grassi has also classified the mosquitoes
employed in the negative inoculation experi-
ments, and he has found the Culex pipiens to
be the most common of the mosquitoes which
are diffused even in non-malarious places.
He adds that the gray mosquito, which Ross
has proved to be the propagator of the ma-
larial parasites of birds in India, is none other
than the Culex pipiens. Ross himself has
seen that the parasites of the estivo-au-
tumnal fevers of man do not develop in
the body of this mosquito.

These researches, conducted with all the
care and with all the precautions possible,
give the first experimental proof of the fact
that malaria is produced by inoculation; they
demonstrate besides that the Culex pipiens,
the most common mosquito, is innocuous for
man; and they indicate that those species
which Grassi has found exclusively in ma-
larious places are capable of transporting the
infection.

But is malaria contracted solely by inocu-
lation? Certainly inoculation is the only
means up till now experimentally demon-
strated. Apropos, Bignami has made other
researches directed to the obtaining of new
proofs for or against the theory of inocula-
tion. He has made some experiments which
demonstrate that the malarial parasites of
the blood do not resist even a brief desicca-
tion; still more, he has seen that in the peri-
bronchial glands of individuals coming from
highly malarious places no form is found
which could be interpreted as of a parasitic
nature, such as might be presumable if the
malarial germs were inhaled like dust.

In his turn Bastianelli has been occupied
together with Bignami in the morphological
study of the malarial parasites, putting it in
relation with the research on the biology of
the parasites external to man; directing it,
therefore, principally to those parasitic forms which, according to the opinion of many, are destined to ensue in the environment life of the parasite—that is, the semilune of estivo-autumnal fevers and the flagellate bodies. Opinions were divided on the structure of the semilune, and nothing was known of the structure of the flagellate bodies in man.

The results of these beautiful morphological researches may be summarized in a few words:

1. The semilunar bodies constantly contain chromatin, which is found in the central part of the semilune in a clear space—that is, the nucleus of the parasite. This result was constantly arrived at with the study of the preparations in which the humidity swelled the nucleus and its chromatin, and with another method Grassi and Feletti have arrived at the same conclusions.

2. The flagella are constituted principally of a protoplasmic part and of a central part of nuclear substance.

3. The flagella derived from the masses of chromatin of the nucleus of the semilune and of the large bodies not divided of tertian, which become swollen, reach the periphery, and lengthen in the form of flagella.

4. Some flagellates exist whose flagellum is constituted exclusively of protoplasm, the central part remaining undivided, constituted by the chromatin of the semilunar body.

This observation may be invoked as supporting the doctrine that the flagella have importance in the propagation of the species external to man.

Meanwhile it is certain that Bastianelli, Bignami, and Grassi have succeeded in observing the cultivation of the semilune of man in the body of the Anopheles claviger Fabr. (synonym A. maculipennis Meig.). Consequently Grassi maintains that this large mosquito with four spots on its wings, already declared by him to be the true index, the true spy of malaria, is the definite host of the malarial parasite of estivo-autumnal fevers, and is, therefore, a terrible enemy of humanity. That which happens in the environment to the other forms of malarial parasites of man, and more especially that which happens to them in the other mosquitoes of malarial places, is now being studied. To-day we can add that also the parasite of the spring tertian develops in the body of the same Anopheles claviger.

Meanwhile Fermi has tested a hundred substances believed to be culicifuge, using them either alone or combined in the form of a cutaneous ointment, the most practical and the most reconcilable with the habits and the necessities of life in the open air of the workers in the season and in the places where malaria exists. He has thus demonstrated that two substances at least have all the necessary qualities for this scope, and with them he proposes to make extensive prophylactic experiments on man in the coming malarial season.

This year Celli himself has been able to make a large experiment of preservation of bovine malaria, in two contiguous farms worked by Lombards, and cultivated by means of irrigation.

In the Cervelletta farm, where in the past this homicidal disease was extremely prevalent, all the cows were always kept in the stalls, to prevent their being attacked by ticks, and if any of these appeared, they were quickly removed. A regular treatment with arsenic was also adopted. Of all this vast herd, not a single animal was attacked with malaria, while in the contiguous farm of Bocca di Leone, where no prophylaxis was adopted, and the cows were allowed to graze in the fields, in one week all were taken ill, and fifty-four per cent of them died from malaria; and Miss Foà, in Grassi’s laboratory, found in one an enormous quantity of the Rhipicophilus ammulatus, or the same species of tick which in America propagates the same disease.

The financial importance of this experiment is evident. In other times, even very near to ours, this bovine malaria has destroyed here in the Campagna whole herds of milch cows, extensive irrigation works, and large industries in cheese-making. Today, instead, science can suggest the means of avoiding such economic disasters.

Now coming to the second of the colossal problems above indicated—that is, to the natural immunity from malaria, and the mode of artificially reproducing this immunity—it must be admitted that the researches apropos are very few, because they are very difficult and very expensive.

Two years ago Celli and Santori found that inoculations of the serum of the blood of animals immune to every species of malaria succeeded in lengthening, sometimes extraordinarily, the period of incubation of experimental malaria.

The researches carried out during all the past season of fevers have led to the following conclusions:
1. The principles on which serum immunity and serum-therapy are founded are of no value for malarial infection. In fact, it is beyond question that the serum of the blood at the beginning of the fever contains a pyrogenic toxin, and it is certain that the same serum in the defervescence of the fever has not an immunizing property either for the patient himself (active immunity) or for others (passive immunity), and for the latter it has no curative action, just as the serum of the blood of spontaneous cures and of individuals immune to malaria has no immunizing action. They are continuing their experiments to discover whether the cellular elements of the blood in the above mentioned conditions contain some toxic principle, respectively immunizing or curative.

2. The inoculation, even abundantly repeated, of the blood of bovine malaria does not protect man from his malaria, just as the serum of the blood of cattle cured from this malaria does not protect him.

3. Neither have experiments of opoimmunity, in respect to ophotherapy, with the juices of organs (brain, spleen, bone-marrow, lymphatic glands) of cattle which live in a very healthy state in malarious regions, hitherto given results positively favorable to man.

4. The serum of the blood of the horse treated for a long time with large progressive doses of quinine has proved to be inefficacious both as a preventive and a curative of malaria in man and animals.

5. Immunity against the natural infection of malaria may be congenital or consecutive to long-continued disease. Congenital immunity is sometimes maintained with a life of toil, with diminished alimentation, with excessive work, and it is independent of the faculty that the skin may have of being punctured by mosquitoes, and of the degree of reaction which may follow these punctures.

Congenital immunity is more stable than consecutive; it also rarely resists the experimental infection—that is, inoculations of large doses of blood containing many malarial parasites.

After these researches it is more than ever urgent that the mechanism of such immunity be thoroughly studied in the animals nearest to man. Making it in cattle is too expensive; the Society cannot give the means which the above mentioned American authors received in profusion.

Fortunately Dionisi has found parasites perfectly analogous to those of human malaria in some species of bats; that is, he has found a pigmented parasite, similar to one of those of the spring fevers of man, and a parasite without pigment, resembling that of the estivo-autumnal fevers of man. And Casagrandi, in his researches on malaria of animals of the Pontine marshes, has observed parasitic forms within the red corpuscles of a small mammal of the Campagna.

To terminate the list of the researches made by the members, Professor Celli adds that Dionisi has studied in the past summer and autumn how anemia is produced in the various malarial infections, and what quantitative and qualitative alterations of the blood take place in nephritis from malaria and in hemoglobinuria; while, on the other hand, Santori has prepared a map of malaria in the Province of Rome, on the basis of the statistical and meteorological observations of the last decennium. [It is perhaps advisable here to note that malaria now rarely, if ever, occurs at any season of the year within the walls of the Eternal City.] All these investigations will be published in extenso in the Transactions of the Society.

And now and always fuit opus! The members are continuing their studies, and they rely on the pecuniary aid which the Society willingly gives them for the payment of the necessary expenses.

Meanwhile, in India, England has for the study of malaria placed such means at the disposal of Ross as to enable him to telegraph from Calcutta to Edinburgh a full account of his splendid researches.

Germany has equipped, through the initiative of the Colonial Society, a great scientific expedition to Africa, with Koch at its head, who during the past summer visited Rome.

Belgium has provided 50,000 francs for the study of malaria in the Congo.

And thus the civilized nations, after having subdued malaria in their own house with great and expensive irrigation works, are preparing to redeem their colonies.

Italy, said Professor Celli, where malaria keeps about five million acres uncultivated, and every year on an average attacks two millions of its most useful sons, and kills 15,000 of them, cannot, must not, remain behind in this noble scientific competition! It in the past has done its duty; that it will fulfil it also in the future is the most fervent vow which from the bottom of their hearts they raise in this temple of science at the first meeting of the association.
Original Communications.

AN OPHTHALMIC CLINIC AT THE JEFFERSON MEDICAL COLLEGE HOSPITAL.

By G. E. de Schweinitz, M.D.,
Professor of Ophthalmology.

A number of interesting cases await our consideration, and from among these I shall select several which illustrate important points in ocular therapeutics.

CASE I.—Abrasion of the Cornea and its Treatment: (a) with Non-infected and (b) with Infected Surroundings.—This patient, a man aged about twenty and a shoemaker by trade, was struck in the right eye yesterday with an auger bit. He came at once to the hospital and was cared for by the resident surgeon until the opening of the Dispensary for Diseases of the Eye, about six hours after the injury. A drop of two-per-cent solution of fluorescein instilled into the conjunctival sac (which drug, you remember, colors green any spot on the cornea deprived by injury or disease of its epithelium) revealed two large abrasions of the cornea and a number of linear lesions passing like ridges across its face. There was no unhealthy secretion on the conjunctiva, no disease of the ciliary margin, and, most important of all, normal
lacrimonal passages. A drop of sterile atropine solution was put into the eye in order to prevent or, perhaps, to relieve congestion of the iris; the conjunctival sac was thoroughly flushed with a four-per-cent solution of boric acid, particular care being taken to cleanse the ciliary borders; and the lids were immobilized by a compress bandage. It is just twenty-four hours since this dressing was applied, and now you observe the eye is quiet, the abrasions have healed, as is proved by the negative result of the fluorescein test, and the corneal mirror is bright and normally reflects an object passed in front of it.

I have dwelt at some length upon this case because it teaches an important lesson—the lesson that every abrasion of the cornea must be scrupulously protected from infection until the epithelium has been regenerated. Just such abrasions as these will, if neglected, become the gateways of infection through which pathogenic bacteria pass to inoculate the true corneal tissue and produce the various types of sloughing ulcer of this membrane. These bacteria have their habitat in the conjunctiva, the ciliary borders, the nares, and the lacrimal passages. Of the various microorganisms, we are most likely to encounter in typical serpiginous ulcers the pneumococcus—that is, the Fraenkel-Weichselbaum capsulated diplococcus—and in other types of sloughing ulcers staphylococci and streptococci, or a mixed infection. Schizomycetal infection, which occurs as a rarity, is practically always due to the aspergillus fumigatus.

Suppose this abrasion had occurred on a cornea surrounded by infection—for example, on the cornea of this girl, from whose lacrimal sac, you observe, a thick pus is made to exude upon the slightest pressure. What would have been the treatment? That would have depended somewhat upon the condition of the abrasion. If this was still recent, the conjunctival cul-de-sac would have been sterilized (as well as this is possible) by frequent flushing with a saturated boric acid solution, or following Haab's recommendation, with a one-fifth per cent solution of sulphate of zinc in 1:10,000 of bichloride of mercury; the canaliculus dilated, if it is necessary; and the lacrimalonasal duct thoroughly irrigated with some antiseptic solution—for example, 1:8000 bichloride of mercury, 1:6000 formaldehyde, 1:500 nitrate of silver. Naturally, the patient would have been under observation and 'he collyria and lacrimalonasal irrigations employed as frequently as necessary to keep the surroundings reasonably clean.

If an abrasion of the cornea should develop a suspicious haziness of its border, or careful bacteriological examination should demonstrate infection, then proper prophylaxis would demand an application to the abrasion itself of some chemical substance which combined the properties of a germicide and a caustic. Of these I am inclined to think the best are nitrate of silver two-per-cent, carbolic acid, tincture of iodine, and formaldehyde 1:50, care being taken that only the abraded surface, which can be accurately outlined by means of the fluorescin, is touched. Recent investigations have indicated that in pneumococcal infection of the cornea the colonies are deep, and perhaps agents such as I have described do not reach them. Therefore, if any sign of spreading of the infection should appear it would be advisable to destroy that area with a light touch of the galvanocautery. Please bear in mind that I am speaking of an abrasion of the cornea which has become infected by surrounding purulent matter, or if it has not become infected, is in grave danger of this accident, and not of the treatment of ordinary abrasion of the cornea with non-infected surroundings as before described and illustrated by the patient.

Case II.—Dacryocystitis and its Treatment; Indications for Excision of the Lacrimal Sac; Conditions which May Be Mistaken for Dacryocystitis.—The second patient, a girl aged twelve, has been coming to the dispensary for a long time on account of a purulent discharge from the left lacrimal sac, associated with typical inflammation of the surrounding conjunctiva and margin of the lid, the so-called lacrimal conjunctivitis. Exactly when this affection began is not clear from the history, nor is it important. It has existed now for many months, and the treatment has been division of the canaliculus, introduction of probes to restore patency to the lacrimalonasal duct, irrigations with various antiseptic substances, and intranasal treatment to relieve rhinitis, the evidences of which are still manifest, and to remove a hypertrophied turbinated body. To restore the patency of the duct large probes (we are here accustomed to use Bowman's probes as high as No. 8, having a diameter of about two millimeters) have been employed. Dr. Theobald, however, does not believe that probing is thorough until a probe of about twice that diameter has been used, and in about two-thirds of all his cases,
including children as well as adults, he introduces his No. 16 probe, which has a diameter of four millimeters. I think there is very little doubt that a probe of this size would readily pass through the duct of the present patient, but I am inclined to think that the results would be no better than those reached with the No. 8 or No. 10 Bowman probe, because the lining of the sac and of the nasal duct is in a state of chronic inflammation comparable to the same pathological condition present in the bladder in chronic cystitis. If subsequent treatment continues negative, I shall try the operation of excision of the lacrimal sac and lacrimalonasal duct—that is to say, excision of the pyogenic membrane. The sac is exposed by dividing the overlying integument layer by layer, the incisions being curvilinear. It is difficult to dissect the wall of the sac from the skin and from the bone, but it is essential that it as well as the nasal duct shall be thoroughly removed.* Some surgeons prefer to destroy the sac by means of caustic or the galvanocautery. As the result of this operation, if successful, the purulent discharge ceases to appear in the eye, although the drainage system is obliterated and necessarily there is epiphora. Should this epiphora become exceedingly annoying, it would be permissible to excise the lacrimal gland; but most patients, if one may credit the accounts of those who have done the operation most frequently, do not complain of the epiphora except in windy weather, or at least do not complain of it excessively, and naturally very much prefer it to the purulent discharge.

Because a purulent material appears in close proximity to the lacrimal sac one must not be too ready to diagnosticate lacrimal sac-disease. In other words, a fistula of the orbit opening just above the inner canthal ligament may be due to disease of the ethmoid or anterior frontal cells. In a case of this character recently under my care the lacrimalonasal duct had been probed time and again for more than eight years, although dacryostenosis as such did not exist, for the carious track led into the region of the anterior ethmoidal cells, or that detached portion of them, at least, to which the name lacrimal cells is now given.

Occasionally we encounter disease in front of the lacrimal sac—so-called prelacrimal abscesses and prelacrimal cysts—which does not actually arise from the sac itself, but which may be the result of an injury, of the breaking down of a gummatous growth, of an abscess, and readily may be mistaken for lacrimal sac-disease itself. The passage of a probe, of course, would indicate that the pocket did not lead into a sac terminating in the duct, but into a cul-de-sac. More rarely, buccal fistula occurs below the margin of the orbit and might be mistaken for lacrimal fistula. Proper investigation with a probe would settle the differential diagnosis.

Case III.—Acute Contagious Conjunctivitis.
—This child, three years of age, shortly after convalescing from an attack of influenza of the pulmonary type, was attacked with an inflammation of the eye having the following characters: Deeply injected conjunctiva, through which are scattered small hemorrhages; swollen and edematous lids; and free secretion of mucupus, which collects in strings and especially in masses at the inner canthi. In other words, this is a case of acute contagious conjunctivitis, sometimes called epidemic conjunctival catarrh, and vulgarly known as "pinkeye."

In the conjunctival secretions of many of these patients a small bacillus—known as Week's bacillus—may be found, which is believed to bear a specific relation to the disease. It would seem, however, that an exactly similar conjunctivitis is often caused by the pneumococcus and perhaps by other microorganisms. I shall have the secretion examined and determine exactly the bacterial contents. The treatment should be: Isolation, if possible, as the disease is markedly contagious; frequent conjunctival irrigation with a saturated boric acid lotion, or with mercuric chloride (1:10,000); and frequently changed ice compresses if the swelling of the lids (which should be everted once a day and the tarsal conjunctiva brushed with a one-per-cent solution of nitrate of silver) is considerable. Under such treatment the duration of the disease is, so far as the acute stages are concerned, from four to six days, although it requires about two weeks for the restoration of the conjunctiva to full health.

Cases IV and V.—Relapsing and Subacute Catarrhal Conjunctivitis.—The patient, aged twenty-five, a clerk by occupation, in good general health, has been subject to "attacks of conjunctivitis" for a number of weeks. The ordinary symptoms of acute catarrhal conjunctivitis appear under treatment gradually to subside, but the mucous membran—

---

* At the next clinic this operation was performed and a greatly thickened lacrimal sac and nasal duct removed.
never regains an entirely normal appearance, being somewhat congested and a little opaque, while the margins of the lid are somewhat reddened. The other patient, a man somewhat older and a tailor by trade, presents a similar conjunctival condition, described in a word as subacute conjunctivitis, but has no history of acute exacerbations. As you probably know, in recent times, in many cases of subacute conjunctivitis, particularly such as stubbornly resist treatment, a diplobacillus will be found in the secretion, originally isolated by Morax and Axenfeld abroad and especially studied in this country by Gifford. The germ has also been found here by myself in some cases in the Philadelphia Hospital, and by Dr. Sweet in a number of cases in this clinic. I will therefore make a culture from each of these conjunctivæ and later report the results. Should the bacteriological examination reveal the diplobacillus of Morax and Axenfeld, the proper local treatment will be the application of sulphate of zinc (from one-half to two per cent, according to circumstances), under the influence of which diplobacillus conjunctivitis is rapidly cured. But do not allow the search for microorganisms to cause you to forget other important etiological factors in subacute and recurring conjunctivitis, the two most important of which are refractive error and rhinopharyngeal disease. Therefore each of these men will be investigated from these viewpoints and treatment directed according to the findings.

**LUMBAR PUNCTURE FOLLOWED BY RELIEF OF SYMPTOMS—FOUR CASES.**

*By J. Madison Taylor, A.B., M.D., Philadelphia.*

It is particularly important to put on record sound testimony in behalf of any therapeutic measure which offers the smallest possibility for relief of those conditions for which little can be expected.

Too frequently sufferers from almost helpless states fail to get the attention they deserve. A fuller investigation of methods, exploited hopefully, but found disappointing, may result in important practical modifications which shall afford sooner or later marked lessening of the degree or length of those distressing states. To be sure there is, in many instances, only the prolongation of a conspicuously foredoomed life, but the meager item of hope will occasionally blossom into unexpected possibilities, and the finality may even be a recovery, which is assuredly the highest joy to the consciousness of the physician, even though the succored one become little more than a surviving wreck.

It is with this thought in mind, then, that I present the curtailed notes on the cases of four children suffering from certain forms of meningitis, in whom the symptoms due to intracranial pressure and the attendant distressing phenomena were definitely relieved.

The importance and difficulty of obtaining relief from increased intracranial tension has long been recognized, and various devices have been suggested by which this might be most completely and safely secured. T. Clage Shawe in 1889 suggested trephining for the relief of the brain pressure, which was done with fair effect later by Harrison Cripps. This measure was welcomed by Battey Tuke, who suggested laminectomy. Then a number of others suggested divers methods and operations to secure relief from hydrocephalic tension, including the bold plan of W. W. Keen to tap the lateral ventricles, which I myself saw him originally demonstrate and subsequently and successfully perform. None of these plans afforded such safety along with practical utility as Quincke’s operation (1891) of puncturing the spinal canal at the second, third, or fourth lumbar vertebra for the relief of hydrocephalus. Von Ziemmsen (1893) approved of this plan and suggested its use in tubercular and purulent meningitis, and Lichtheim (1893) called further attention to the diagnostic importance of the operation as furnishing evidence of the presence of infective bacterial or other toxic quality in the fluid thus removed. Furbinger experimented largely in the field, reporting a total of eighty-six punctures in his first paper. Wentworth brought down upon himself the sharp criticism of a number of surgeons and others, including myself, by his report of a number of punctures upon healthy infants. He demonstrated, however, most conclusively, that with due precaution there was no danger attending this procedure, and my experience leads me to agree with his conclusions.

A number of observers have recorded their experiences with this operation, some of whom (Freyhein, Furbinger, and others) testify to its value as both a diagnostic and therapeutic measure.

Monti, in a series of twenty-one cases, asserts that in tuberculous meningitis it offers nothing for diagnosis or relief. In acute
cerebrospinal meningitis, reliable indications were afforded and frequent repetitions of puncture exercised a favorable influence upon certain cases when done in the earlier stages. Stadelman, in conclusions drawn from a number of cases of various forms of meningitis, regards the measure as without diagnostic or therapeutic value.

In the cases presented here little was learned from the examination of the fluid, no tubercle bacilli were found, and in some no cultures were made to demonstrate other bacteria. In all there was a certain proportion of relief obtained, enough to justify the expectation that under more favorable conditions and fuller studies improved conclusions might be reached; certainly enough of advantage was obtained to warrant a further employment of this safe measure.

Three of my cases were of immediate gravity, and one was seen late, two of them only after chronic conditions had become established. It would seem reasonable to expect that in conditions of acute cerebrospinal overtension from various causes, with delirium, headaches, uncontrollable vomiting, spasms, and other evidences of cortical irritation, a withdrawal of fluid might materially relieve and aid other rational measures.

Case I.—Chronic leptomeningitis; purulent otitis media. A boy of two and a half years was brought to my clinic at the Children's Hospital in November, 1896, who had been treated in the wards for some weeks previously. The records there gave the diagnosis as cerebral palsy, etc. Eyesight poor since birth; exophthalmus, hypertension of globe, inability to close the eye completely, nystagmus, no fundus lesion, ptosis (A. G. Thomson). Athetosis of right hand; restless, frequent movements. No cardiac lesion. Unimproved.

The symptoms pointed to an asymmetrical diplegia and were difficult to define, the child being deaf and blind, and, except for the good care recently received in hospital, showed evidences of much neglect. My colleague, Dr. Chas. W. Burr, saw the case with me, and expressed a guarded opinion.

The history elicited was mostly negative and contradictory. The parents were large, vigorous folk, much given to drink; the father was described by the mother as a powerful, violent man, habitually intoxicated. This was the eighth child; others all robust. Three had died of membranous croup. This boy was not so strong as the others, but fairly well; always rather dull, but he could walk and speak a few words before his illness.

Our examination of the boy in hospital showed a fairly well grown and nourished child, with wide-open, staring, gray-blue eyes; partial ptosis, slight lateral nystagmus, increased on being disturbed; mouth constantly kept open, sores on lips, fairly clean tongue; normal abdomen; skin dry and flaccid. In the region of coccyx there was seen a depression which appeared to be the result of an abortive spina bifida. The spine was straight; no tenderness; the feet had a tendency to equino-varus. The head was retracted; the left ear discharged offensive pus; the child uttered an occasional hoarse, high-pitched cry or whine. For the past six weeks there had been a frequent rolling of the head from side to side; eight weeks ago one convulsion occurred, since which the child has been in the present state of helplessness and apathy. The head was of fair size and shape. Diameters: glabella to inion, 16 centimeters; occipitomental, 18 centimeters; biparietal, 13½ centimeters; opipitofrontal, 15 centimeters; frontomental, 14 centimeters; circumference, 45 centimeters.

The mother declares there was never any anterior fontanel; all are now closed. No craniotabes; there was a possible tenderness on deep pressure posteriorly. More or less constant athetoid movement persisted, except when asleep or long undisturbed, especially of the right arm and hand, evidenced also by the other limbs at times. The superficial reflexes were inactive, the deep ones somewhat increased on reinforcement; a slight ankle clonus easily exhausted; sensation normal or increased. There was a loose cough and a temperature varying from 98° to 100° F., lower in the afternoon. Percussion of chest normal, except at left apex. Auscultation negative. Heart normal; splenic dulness increased; liver dulness normal; glands not enlarged, except a few of the cervical glands slightly. Digestion fairly good; swallowed slowly; bowels loose; mucus and feces passed involuntarily. Abdomen normal; urine passed involuntarily, negative chemically.

Ophthalmoscopic examination (Hansell): Pupils dilated, reacting doubtfully to light. Right eye: no swelling, no atrophy of optic disk; no choroid blotch. No optic neuritis of either eye. Left eye: no swelling, no hemorrhages; coloboma of the nerve sheath, extending as far as can be discovered—not in both eyes; ground honeycombed.

Various lines of treatment were tried
with little result, including thyroid feeding. Finally it was determined to use lumbar puncture, and Dr. Max J. Stern, on February 11, drew off about thirty-five cubic centimeters of fairly clear cerebrospinal fluid. No pain was evidenced under operation, the child falling asleep almost at once. After this there was a certain amelioration of symptoms, notably of the restlessness. The athetoid movements almost ceased, except to return slightly when unusually disturbed.

On March 16 a second puncture was made, drawing off forty-one cubic centimeters, which was again reported to be bacteriologically negative. There was now, and for so long as the child remained in the hospital (three weeks), a marked improvement. The restlessness ceased, the color improved, and in consultation with several of my colleagues we felt assured the child could both see and hear a little. However, the destructive changes in the centers had been too long-continued for actual repair, and all one could possibly expect was such relief of the pressure phenomena as was actually obtained.

It is reasonable to infer that earlier interference would have resulted more favorably.

Case II.—Acute hydrocephalus, "meningitis serosa" (Quincke). Rapid aggravation of symptoms, till death seemed imminent. Lumbar puncture; instant cessation of distress. Recovery from all acute symptoms.

I was called in consultation with Dr. Edwin Rosenthal January 2, 1898, to see a baby eight months old who was in constantly recurring convulsions, which were repeated with increasing force and length, especially on attempts to nurse at the breast. The parents were young and entirely healthy looking, living in comfortable surroundings. This was the fourth child; the others perfectly well. This baby was fed upon the breast, the supply of milk being ample and of good quality. A month before the baby had some febrile attack followed by several days of incessant vomiting. Dr. Rosenthal was called in only a day before, and he summoned me at once. The recurring convulsions steadily growing more severe, the bulging fontanelles, the fixed, staring eyes, with irregularly dilated pupils, which failed to react to light, strongly retracted head, the prolonged unconsciousness and continued clonic spasms in the left side of the body between the larger convulsions, all formed a grave and menacing picture.

I found that the superficial reflexes were absent and the deeper ones only moderately obtainable, though they fluctuated and at times were in excess. The face was almost constantly cyanosed, the pulse feebly irregular and very quick; the heart sounds much confused, but apparently free from adventitious sounds. I advised the operation of lumbar puncture without delay, and had the child removed to the Polyclinic Hospital, where the mother, remained with it. Dr. S. K. Morton met me at once and operated, withdrawing thirty cubic centimeters of cerebrospinal fluid. The child gave no evidence of discomfort (ethyl chloride was used locally); indeed, there was the most marked relief at once evidenced upon the child's face, as well as throughout the whole body. The spasmodic motion ceased as soon as the flow became established, and the child slept soon and passed a most comfortable night.

A few hours afterward examination showed a marked lessening of the tension in the fontanels (the measurements of the case have been lost); the pupils responded to light and seemed almost normal; the pulse became steady; and the spasmodic movements decreased. This child is now under observation for over a year, and is very well except for a slight condition of hydrophalic deformity.

Case III.—This case was reported at length by Dr. Edwin Rosenthal (who had me in consultation) in Pediatrics of November 1, 1897, and I shall only briefly recapitulate the main facts: Boy of ten months. The family history was filled with evidences of constitutional nervous instability. This was the third child, others having died of "convulsions," etc., and was breast fed only. Three months previously there had been some form of acute febrile disorder, at which time the head began to enlarge. Two weeks before we saw the babe a series of acute phenomena supervened, which culminated in the present serious state of acute hydrocephalus. The constant local spasms were for some time on one side only, and then changed to the other, finally alternating back and forth; they were of varying force, from twitchings to severe convulsions of both sides when at their worst, and only rarely absent while asleep. Sensation present, though at times impaired. The eyes remained unchanged in their axes, except during large convulsions, when the pupils converged and were equally contracted, but at times were dilated. A competent medical student remained in charge for several days, who kept record of the states. There was no vision that we could demonstrate. The
head was enlarged in a curious globular fashion, the temporal region overhanging the ears. The measurements, which are recorded, were frequently repeated. I became skeptical as to the variations after lumbar puncture, though I believe they are in the main correct. This variation was enormous, and the relief by tapping very marked. Temperature, mouth and rectum, normal. Respiration of the Cheyne-Stokes variety. The knee-jerks could scarcely be elicited at this time, but after tapping became normal. The superficial reflexes were impaired.

Dr. Stern did lumbar puncture between the third and fourth lumbar vertebrae, and eighty cubic centimeters of fluid was withdrawn, the flow being allowed to cease spontaneously. No tubercle bacilli were found (Dr. Abbott, of city laboratory). The child became comfortable and quiet as soon as the fluid began to flow, and slept well for several hours; the color and respiration became normal, the pupils resumed their reaction to light, and the pulse fell from 180 to 145. The following day the symptoms became severe again; the knee-jerks were normal, however. Pressure on the fontanels caused convulsions; the head measurements were increased, but not so great as at first. The child had taken nourishment fairly well and retained it, and the bowels responded normally to calomel. The urine passed in the interval was of a curious olive-green color and showed traces of albumen, some sugar, but no casts. These soon disappeared. Respiration became Cheyne-Stokes again at times. On the third day the head measurements were again increased. Symptoms of exhaustion supervened, and the child died three days later. We feel confident that earlier interference would have resulted more favorably.

Case IV.— Probably simple posterior basic meningitis. Boy of seven months, of healthy parents, good ancestry, and breast fed, developed symptoms of meningitis with convergent strabismus, general convulsions, retracted head, etc. I took the babe and mother into the Polyclinic Hospital in November, 1898, and performed lumbar puncture, drawing off only about ten cubic centimeters of fluid. In this we found no bacilli. Pressure symptoms were at once relieved, and the child slept well and took the breast comfortably. The case was kept in the hospital for ten days and is still under observation (four months now), and seems to be perfectly well.

Certain conclusions seem plain to me in view of these facts. When there are marked symptoms of intracranial tension imperiling life in many directions, not the least of which is the interference with sleep and the nutritive processes, lumbar puncture seems a useful and safe procedure. It is an operation which any competent medical practitioner can perform, the dangers being few, and almost no evidence is adduced to show that damage has resulted.

Distinct relief can be expected to follow in many instances, though the testimony of observers varies. Many series, too numerous to quote, have been recently recorded, but the conclusions are practically those of Fleischman (Deutsche Zeitsch. f. Nervenheilk., 10, 1897).

MORPHINE IN UREMIA.

By J. W. Meek, M.D.,
Camden, Arkansas.

In the Journal of the American Medical Association of July 23, 1898, I read with interest an article by Professor Tyson on the use of iron and opium in chronic Bright’s disease, and in the November and January numbers of the Therapeutic Gazette the editor apparently gives an unqualified endorsement to his conclusions. I need hardly mention that these conclusions are in the main against the use of opium and its preparations to control the nervous phenomena that constitute so distressing a feature of chronic interstitial nephritis. Both articles invoke the name of the late Professor Loomis to strengthen this position, yet I must insist that both fail to quote Loomis airtight. In the United States Professor Loomis is universally credited with having first used morphine hypodermically to control uremic convulsions, but these articles insist that he only recommends it in the convulsions of acute nephritis.

Now I ask every one who feels an interest in this subject to read carefully Loomis’ work, edition of 1889, from page 577 to page 616 inclusive, and then “let us reason together” and see if his written words will sustain the interpretation given by such distinguished authorities as Professors Tyson and Hare. In the November number of the Therapeutic Gazette it is stated that “Professor Loomis’ position has been much misrepresented,” and in the January number, on page 22, it is stated that Loomis was “careful to limit its use (morphine) to the uremia of acute nephritis, and did not commend its employment in the
uremia of chronic nephritis." Further, it is stated "this fact is not generally known." Against this I will quote Loomis, on page 616, Treatment of Chronic Interstitial Nephritis, where he uses the following words: "For symptoms or complications that demand a narcotic or anodyne, *opium* is to be used in preference to all others." Now certainly all will admit that convulsions is a condition that demands an "anodyne or narcotic," and no doubt he meant convulsions in the expression "symptoms or complications."

A careful reading of Loomis' work will show that he treats of uremia in a chapter preceding his treatise on the various forms of nephritis, and in writing of the occurrence of uremic symptoms in the various forms of renal disease he refers back to the chapter on uremia for the treatment of the same. In the treatment of all the forms of renal disease he never mentions opium nor its preparations, not even in acute nephritis, except to recommend it in *chronic* disease, on page 616, as I have already quoted. Some readers have been misled by the expression "acute uremia," which he says on page 577 "may occur in *chronic* as well as acute renal disease." He never says "uremia" occurring in acute renal disease—it is always "acute uremia," by which he evidently means a sudden development of same.

I know neither Professor Tyson nor Professor Hare would intentionally misrepresent Professor Loomis, and I ask them both to read his article on the lines suggested.

Again, Loomis in a little work entitled "Treatment of Bright's Disease," issued by Geo. S. Davis, says, on page 15: "Since uremic phenomena are not specifically associated with any one, but may occur in connection with all forms of Bright's disease, they may properly be described once for all." Again, on page 101, in the treatment of cirrhotic kidney, he says: "Acute uremia occurring in cases of cirrhosis will call for the treatment already described." And I need hardly add that treatment places opium in the front rank.

It would be presumption in me to set up my opinions against those of Professor Tyson and Professor Hare, but I must state that morphine subcutaneously has in my hands, cautiously given, been a nepenthe, as Poe would call it, to some of my incurable patients. The uremic asthma that, like Macbeth, "murders sleep" has almost invariably been relieved by a hypodermic of one-fourth grain of morphine and one one-hundred-and-fiftieth grain of atropine, and what would have been a hideous night for patient and friends has been made one of rest and refreshment by the above remedy. No one will deny that it has its limitations, and all who recommend it should urge caution in the beginning until the patient's tolerance is tested.

Truly "experience does not teach all alike," as we find such able observers as Hare and Tyson on the one side, and Osler and Ringer arrayed against them on the opposite side, on this subject.

I will add a quotation from Hare's "Practical Therapeutics," page 292, edition 1897: "Opium acts as a preventive of tissue waste, increasing the elimination of urea and other results of nitrogenous breakdown." I have the highest respect for the above named authority, and if opium increases the "elimination of urea" it can scarcely fail to be beneficial in uremic toxemia.

**

To this article Professor Tyson has kindly made the following reply:

To the Editor of the Therapeutic Gazette.

I thank you for the opportunity to read Dr. Meek's communication on the use of opium in chronic interstitial nephritis, in which he refers to my own paper on "The Use of Iron and Opium in Bright's Disease," read before the Section on Practice of Medicine of the American Medical Association at Denver in 1898, as well as to your papers in the Therapeutic Gazette. The statements in my paper are based on my own experience and continue to be confirmed by my observation, though I am glad to realize that opium is being more and more cautiously used, particularly in the interstitial variety of chronic nephritis, and therefore that accidents are more infrequent. My reference to the late Dr. Loomis was not based on a study of what he wrote on the subject, because I never read what he himself wrote, but was based on what he said to me personally the last time I saw him, in the summer of 1893, when he presided over the meeting of the Association of American Physicians in Washington.

As to acute and chronic uremia I see no essential difference between them; indeed, I am rather skeptical as to the existence of a chronic uremia as something separate from an acute uremia. They are both due to the same cause, the retention of a toxic something in the blood which it is the office of the kidneys to remove. In one case the accumulation may take place rapidly, and in another
more slowly. In one the symptoms may arise suddenly, in the other develop gradually. Now in acute nephritis, in which the employment of opium is admissible, the secreting cells of the kidney are still abundantly present, and though damaged are more or less capable of maintaining their function, while in interstitial nephritis they are mostly gone, destroyed in the contracting process or represented by a remnant of cells of feeble function. Under these circumstances, elimination is maintained through the compensatory hypertrophy of the heart, which by pumping more blood through the kidneys causes a more copious filtration of urine feebly charged with urea, which makes up by its increased quantity for the lowered proportion of urea. Now if we dry up this secretion, as we are sure to do if we administer opium, we retain the toxic matter and invite uremia.

These views I have always thought quite compatible with the physiological effect of opium, viz., that it diminishes the elimination of urea. Has not Dr. Meek supported his position by a typographical error, when he quotes your "Practical Therapeutics," page 292, edition of 1897: "Opium acts as a preventive of tissue waste, increasing the elimination of urea, etc." Should it not read diminishing for increasing?

JAMES TYSON.

My views are identical with those of Dr. Tyson as stated above. The quotation from the edition of 1897 of my book on Therapeutics is contradictory of itself, and is due to a misprint, which has been corrected in later editions, where it reads "decreasing" for "increasing." A drug which decreases tissue waste usually decreases the escape of urea, and in the case of opium this decrease is probably due to this cause and to decreased renal activity under the effect of the drug.

H. A. HALE.

ORGANOTHERAPY IN GYNECOLOGY.*

By W. A. Newmann Dorland, A.M., M.D.,
Instructor in Gynecology, Philadelphia Polyclinic; Assistant Obstetrician to the Hospital of the University of Pennsylvania, etc.

The internal administration of organic extracts for the relief of various morbid condi-

* Read before the Barton Cooke Hirst Obstetrical Society of the University of Pennsylvania, Feb. 15, 1899; and before the J. Atkuen Meigs Medical Association of Philadelphia, Feb. 23, 1899.

tions, while generally regarded to-day as an innovation in therapeutics, is in reality of very ancient origin. It is a well known truth, as attested by no less an authority than Pliny, the historian, that the Grecian and Roman schools were accustomed to consume the testicles of asses to restore their dissipated manhood; and from immemorial the drinking of blood has been supposed to restore lost vitality and to act as a tonic of the greatest efficiency. It remained, however, for the eminent Brown-Ségard and his school of followers to initiate as recently as 1889 the new era of organotherapy, and to formulate the theory of the medicinal value of glandular extracts.

While the results obtained from the administration of the testicular juice have not realized the fond anticipations of its enthusiastic advocates as a therapeutic remedy of marvelous capabilities, it must be acknowledged that the impetus imparted by it to the scientific medical world has developed in a line of active investigation and clinical experimentation that has resulted in much of undoubted value to suffering humanity. As one concerned especially in the allied studies of obstetrics and gynecology, there is much of the new organotherapy that, save from a general scientific point of view, creates but a passing interest. It is to a special study of the action of the extracts of the ovary and thyroid and mammary glands that I would invite your attention briefly in this paper.

As we all know, these organic preparations have been employed more or less extensively during the past few years in the treatment of various conditions, especially for the correction of the menopausal symptoms, whether induced or physiologic, and with a varying degree of success. It is not in this class of cases alone, however, that their value has been demonstrated. Various nervous conditions, such as neurasthenia, sexual atony, and certain forms of hysteria, have been materially improved after their administration. In addition, grave systemic disorders, as profound anemia, chlorosis or chloroanemia associated with dysmenorrhea, osteomalacia, myxedema, and exophthalmic goitre, have in many instances and with divers investigators been greatly benefited, while fibroid tumors of the uterus have melted away, and inoperable carcinomata of the breast, uterus, and vagina have been arrested in their process of development or even actually cured, if we accept the statements of the reporters, as there is every reason to believe that we should.
Then, in addition, the knowledge derived from the systematic use of these glandular extracts has wrought a marvelous change in the techniques of the various abdominal operations; for where formerly it was taught that the last vestiges of the tubes and ovaries should be removed in every abdominal section, and one of the objections advanced against the performance of the vaginal hysterectomy was the frequent inability to extract the appendages together with the uterus, to-day it is the aim of every advanced abdominal surgeon to leave at least a portion of the ovary or tube in situ, if not the organs in their entirety, in order to avoid the deplorable sequences of total castration. Conservation of the ovary in hysterectomy and hysteromyomectomy is now the ne plus ultra in the performance of these grave operations.

Ovarian Therapy.—G. E. Curatulo and L. Tarulli,* who have made a careful study of the ovarian functions, believe that these organs have a special internal secretion, whereby they are constantly discharging into the fluids of the body a peculiar substance of unknown chemical composition, but which possesses the peculiar property of favoring the oxidation of carbohydrates and fatty and phosphorized organic substances. When this substance is removed, either by disease or extirpation of the ovaries, or as a natural sequence of the postclimacteric atrophy of these organs, there results the well known series of phenomena characteristic of the “change of life.” If at the time of an abdominal section but a small portion of ovarian tissue be left in the pelvic cavity, the artificial menopause does not occur, and the woman is saved incalculable suffering. The axiom of Christopher Martin† that “physiologically there is no difference between a woman with half an ovary and a woman with two ovaries, while there is a great difference between one with half an ovary and one with none,” should, in the light of this statement, be classed among the imperishable quotations in medicine.

The Italian observers already mentioned further found that in bitches after the removal of the ovaries there occurred a marked and permanent reduction in the quantity of phosphates eliminated in the urine. Here at once may be detected the rationale of the treatment of osteomalacia by castration, in that there is immediately produced a stoppage of the drain upon the systemic phosphates, which instead will be stored up in the already sadly depleted osseous tissue.

As already stated, an interesting fact worthy of note is that it is not necessary for all of the ovarian tissue to be retained in order that the menopausal symptoms be not induced. It has been demonstrated by Arisstoff, as quoted by Routh,* that when one ovary is removed from a rabbit there is at once induced in the remaining ovary a remarkable and rapid hypertrophy whereby the function of the lost organ can be assumed by its fellow. While such a change has not been clinically demonstrated in the woman, it is not at all improbable that functionally the retained ovary in unilateral castration assumes the duties of both. At any rate, we have sufficient clinical data to prove that a mere fragment of retained ovarian tissue is amply sufficient to preserve the full effects of its secretion upon the body functions.

One other step is necessary to complete the chain of argument in favor of ovarian organotherapy, and, fortunately, this has been supplied through the interesting experiments of E. Knauer.† He has demonstrated that the mere presence of the ovarian tissue in the body at some point, and not necessarily in its original situation, will suffice to exert its dominant action over the system. Again experimenting upon the long-suffering rabbit, he has been able to transplant an ovary, completely detached from its original position, to some remote part of the body, as the distal portion of the broad ligament and in the body of the muscles of the abdominal wall, where it has retained its functions and effectively exerted its influence upon the body.

With the two facts thus clearly demonstrated, namely, that the presence in the body of ovarian tissue, however small the quantity, is necessary to preserve the normal secretions of the body whereby distressing phenomena may be prevented, and secondly, that it matters not where this portion of tissue be retained, whether in its normal situation or elsewhere, it is but a simple matter to formulate the corollary that the administration of ovarian tissue or its essence should exert a beneficial effect in those patients in whom this function is absent either as a result of the normal menopause or secondary to disease or total castration.

* La Secrezione Interna delle Ovarie, Rome, 1896.
† British Medical Journal, Sept. 17, 1898.
† Cent. f. Gynäk., No. 20, May 16, 1896.
It is not my intention to enter deeply into an examination of the literature of this subject, but a hasty summary of the clinical reports will be of interest and value in arriving at the results thus far obtained. Werth, of Kiel, claims priority in the employment of ovarian organotherapy to correct the menopausal symptoms, whether induced or natural; his results were most favorable. Federoff* found that in rabbits ovarian and fresh ovarian extract raised the blood-pressure, but diminished the heart's action and slowed the respiration. In the human female the pressure in the radial artery was notably increased after the administration of ovarian. Poehl's ovarian had, in his hands, a marked beneficial effect in the disturbances attending the climacteric, as well as in functional derangements of the ovaries.

Bodon† reports three cases in which he employed Merck's ovarian tablets. The first was a multipara, twenty-five years of age, who presented the symptoms of the induced menopause, a double ovariectomy having been performed six months before. Improvement began on the second day, and in two weeks she was entirely cured. The second case was that of a nullipara, forty-seven years old, whose menopause had occurred two months before. Four tablets of ovarian daily soon cured her. The third case was that of a virgin, eighteen years of age, suffering with menstrual epilepsy, in whom the bromides and other drugs had proved utterly futile. She began with one tablet of ovarian daily and increased the number to ten. In the course of several months the epileptic attacks ceased.

Jacobs‡ prefers a preparation in wine, the daily dosage being five drachms, containing three grains of ovarian extract. His results were as follows: Climacteric disturbances, including vesical irritation, were either relieved or ceased entirely, whether physiologic or following castration. The results were most prompt in patients suffering from chlorosis and dysmenorrhea. The influence of the extract upon reflex psychic disturbances attending pelvic affections was marked. In all cases a rapid and permanent improvement in the patient's general condition was noted, digestive troubles disappearing, and the appetite being improved. Climacteric hemorrhages resulting from neoplasms quickly ceased, while the therapeutic action of the remedy upon the general nervous system was easily observed.

R. Chrobak* administered ovarian extract made from the fresh ovaries of cows to a number of castrated women suffering with the symptoms of the induced climacteric. In one case, after taking two or three tablets daily, the attacks of giddiness, flushes, and sweatings, which the patient had experienced ten or more times in the day, were reduced to three, and disappeared entirely at night. Another patient was entirely relieved of attacks which had been occurring as often as five or six times daily.

Kleinwächter† employed ovarian extract in three cases of neurasthenia associated with dysmenorrhea. One patient was relieved of her symptoms, but in the other two no improvement took place, and the remedy had to be discontinued on account of the increase of the nervous symptoms produced thereby.

B. Sherwood Dunn,‡ in a paper read before the American Association of Obstetricians and Gynecologists, on August 20, 1897, stated that any skepticism which he may have entertained regarding the theory of ovarian secretion and its usefulness and necessity to equipoise of the entire system had been entirely dissipated by the results of experiments made with ovarian substance, or ovarian, in patients who had lost both ovaries, or who were suffering from troubles which in a greater or less degree were due to a diseased condition of the ovaries. He had obtained excellent results from the daily administration of two grains of ovarian in capsules. M. D. Mann, in the discussion of this paper, said that he had used the ovarin in a few cases of amenorrhea in young women. In one case the hemoglobin was actually increased, but it was too early as yet to arrive at definite conclusions. A. Goldspohn stated that he had treated a case of induced menopause following a total hysterectomy with five grains of ovarian administered three times daily. In one week's time the patient was almost completely relieved, although it was necessary to increase the size of the dose.

Mond§ reports a number of cases of reflex nervous disturbances following the natural and artificial menopause, in which ovarian tissue was administered with benefit. Ten

*Wratch, No. 25, 1897; La Gynecology, Oct. 15, 1897.
†Ormosi Hetilap, 1895, No. 42; Cent. f. Gynäk., Aug. 7, 1897.
‡La Polyclinique, No. 23, 1896.
§München, Med. Woch., 1896, No. 36.
tablets (each containing a grain and a half of dried ovarian tissue) were given daily. By the second or third day it was noted that the attacks of flushing, perspiration, and mental depression were less marked. After ten or twelve days, or when about one hundred tablets (corresponding to one hundred and eighty grains of ovarian tissue) had been administered, the nervous disturbances were reduced to the minimum. Patients at the normal climacteric responded most promptly to treatment, their symptoms being decidedly relieved as early as the sixth day. Mond admits that a permanent cure cannot be expected in case the reflex phenomena are dependent upon atrophy or removal of the ovaries, but their severity may be mitigated and the period of disturbance shortened. Large doses should be given for the first two weeks, and then smaller doses continued for a considerable period, to be increased if the climacteric troubles reappear. He emphasizes the importance of preserving a portion of ovarian tissue whenever this is possible in operations upon the adnexa, in order to preserve the function of menstruation. This applies, however, to cases in which the uterus is preserved, since Glaveecke observed, in fourteen cases in which the tubes and ovaries were spared when the uterus was removed, the same disturbances as after castration. The ovaries in these cases usually become atrophied in consequence of their diminished vascular supply.

Mainzer* has reported cases of profound nervous disturbance and hysterical manifestations in the climacteric after double ovariectomy which were successfully treated with fresh ovarian substance. The symptoms, including the disturbance in the vasomotor apparatus, were completely removed or very favorably influenced. The remedy, he claims, is of good service in primary and secondary amenorrhea. He states that it is advisable at the beginning of the treatment to give small doses at long intervals, and from time to time to increase the dose and shorten the interval as the cure continues.

Jacobs† found that by the use of ovarian extract the disagreeable symptoms of the natural or artificial menopause are relieved or disappear. He reported forty cases so treated with excellent success. Rapid improvement was constant in cases of chlorosis and dysmenorrhea. The extract undeniably influences the psychic troubles accompanying genital lesions. It rapidly overcomes the metrorrhagias of the menopause not connected with neoplasms. It causes a rapid and constant improvement in the patient’s general condition, and its therapeutic action upon the nervous system is manifest from the first day. The results of the treatment are usually apparent on the second or third day. Similar results have been obtained by Jayle, as reported by Lissac*, while Stouffe, of Nevelles, and Touvenaint† have treated several cases of chloroanemia associated with amenorrhea by means of the extract, in all of which the anemic symptoms disappeared and the menstruation returned.

Spillman and Etienne‡ administered to six chlorotic females the fresh ovaries of sheep, dried ovarian tissue, and fluid prepared according to Brown-Séquard’s method. Unpleasant symptoms were noted at first, such as abdominal pains, headache, and muscular soreness, with sometimes a slight rise of temperature. In three cases the patients were much improved, the paleness disappeared, the number of red corpuscles increased, and menstruation reappeared. The remedy seemed to act like an antitoxin.

E. Saalfeld,‖ in view of the observations of L. Landau on the oophorin treatment of nervous symptoms occurring in women about the climacteric period, gave oophorin preparations to women suffering from acne rosacea and other cutaneous disorders at the menopause. The results were satisfactory. In a woman aged about twenty double oophorectomy was followed by nervous symptoms, adiposity, and a lichen-like eczema over most of the body. Great improvement followed the use of oophorin, both in regard to the skin eruption and the other symptoms, and the weight was also somewhat reduced. Saalfeld likewise treated cases of acne, and of seborrhea of the scalp with loss of hair, which often occurs in chlorotic women. He obtained good results in these cases, in certain of them better than the results obtained by chalybeate and local treatment. On the whole, though the results were not as good as those obtained in climacteric troubles, he thinks oophorin may be used with advantage in such cases as an aid to external treatment.

Stimulated by these reports of more than ordinary success in the management of one

---

† Dublin Journal of Medical Science, Sept. 1, 1897.
of the most trying conditions that woman is heir to, I have during the past four months been using organotherapy in its various forms in suitable cases. The ovarian extract has been employed in two cases, as follows:

The first, Mrs. S., a widow thirty-eight years of age, upon whom five years ago I performed a double ovariotomy for cirrhotic changes, was for the last three years an intense sufferer from the climacteric symptoms, with especial prominence of the nervous manifestations, and more or less constant neuralgic attacks of great severity in the hands and feet. The patient stated that at the expiration of seven days of the ovarian treatment—three tablets of five grains each being administered daily—the inflammation (meaning the neuralgia) was so diminished in the knees, ankles, and feet that she was able to wear shoes that she had not worn for three years. The rheumatic pain in the shoulders had disappeared, and she was better than at any time during the three years.

The second patient, Mrs. S., twenty-five years old, developed a double pyosalpinx, probably of specific origin. I removed both appendages seventeen months ago. Six months after the operation the climacteric symptoms developed, and were but slightly benefited by the administration of the usual remedies, including the bromides and ammonium chloride. She was then placed on the ovarian extract, five-grain tablets three times daily, and in two days was relieved of most of her symptoms. At the end of a week, however, the unpleasant symptoms arising from an overdose of the extract developed, and the remedy had to be temporarily discontinued. The menopausal symptoms shortly returned, but with diminished severity, and the administration of the extract was renewed in two-grain doses three times per diem with marked benefit.

From this limited personal experience it would be premature to arrive at any definite conclusion as to the usefulness of the remedy in question. If, however, it be taken in connection with the foregoing results obtained by investigators in various portions of the world, we are safe in formulating the following statements:

1. The ovaries, in common with other glandular organs in the body, exert an occult, but very positive, influence upon the general organism.

2. When this influence is removed, either by the natural atrophy of the glands at the climacteric, by destruction of the ovarian stroma from pathologic processes, or by extirpation of the organs, there results a series of distressing phenomena, including hot and cold spells, nervous and mental manifestations, and neuralgic attacks.

3. The administration of ovarian substance or of the extract of ovarian tissue is promptly and very generally followed by a marked amelioration of these symptoms.

4. The average dose required varies from two to five grains of the extract administered thrice daily.

5. Excessive doses of the remedy will be followed by cardiac and nervous manifestations necessitating a diminution in the dose administered or a complete, though temporary, change of treatment.

6. In some cases there appears to be developed a tolerance to the remedy whereby its effects are diminished in intensity. For this reason it is better to begin with small doses and gradually increase the amount as may be indicated in the given case.

TUBERCULOUS PERITONITIS.

By Anna M. Fullerton, M.D.

Cases of tuberculous peritonitis offer an interesting subject for study to the gynecologist, being frequently associated with disease of the pelvic organs of markedly tuberculous character, which has, doubtless, served as the starting-point for the invasion of the peritoneum by the tubercle bacillus.

Strangely enough, even when this local disease is of most aggravated character there may be no manifestation of involvement of other organs of the body outside of the abdominal and pelvic cavities.

The mode of invasion in any given case is often a difficult point to determine. In many cases there is unquestionable evidence that the disease has reached the peritoneum by the vagina, uterus, and Fallopian tubes, as tuberculous lesions are found in all these organs. In other cases the appendages alone appear to be affected, the uterus remaining free. It has been suggested that in those cases in which the invasion appears to have come from within rather than from without the dissemination of the disease has resulted from broken-down mesenteric glands.

In a case of my own very marked enlargement of the mesenteric glands was appreciated when the abdomen was opened for the removal of diseased appendages, the uterus being apparently healthy.
A family history predisposing to the occurrence of tuberculous disease in a patient is not always to be obtained. Nor do we always find a depression of the general health.

Dr. Howard Kelly thinks that pregnancy shows a definite causal relationship to tuberculous peritonitis, and states that in twenty-eight per cent of his cases his patients dated their ailment from a miscarriage or a labor.

The following brief clinical reports of some cases of this kind occurring in my own practice within the past year and a half may be of interest by way of confirmation of the observations so far made concerning this rather obscure malady:

**Case I.**—A widow, aged thirty-one, an American, with bilateral suppurative disease and extensive pelvic adhesions. The operation for bilateral salpingo-oophorectomy was done for her. The pus found in the uterine tubes was demonstrated to contain tubercle bacilli. The patient did not have the appearance of a tuberculous case. She was in good flesh and her color was good. Her mother had died of consumption, and a sister had a sore on her arm, the result of caries of the bones of the arm of long standing. She had been married eleven years and had never been pregnant. Irregularity of the menses, vesical tenesmus, and severe pain in the inguinal regions were the chief symptoms complained of.

**Case II.**—A young American woman, still in her twenties, was found on abdominal section to be suffering with disseminated miliary tubercle of the entire visceral and parietal peritonaeum. The operation was undertaken for the removal of a suppurating ovarian cyst. The pus from this tumor was proved by inoculation experiments to contain tubercle bacilli. Removal of the cystoma with bilateral removal of the appendages was accomplished. As the separation of adhesions had been very extensive it was thought best to use drainage. The patient was septic when operated upon and intensely weak and emaciated. She made a brave struggle for life, however, and recovered with a small fistula at the site of the drainage tube, which later at times discharged fecal matter. I did not expect this patient to live but a few months, as the disease of the peritonaeum was so extensive. Almost a year later her husband wrote me that she was greatly improved in health and desired to return to the Woman's Hospital for a secondary operation for closure of the fistula. This I advised against, as I felt it unwise to reopen her abdomen. She went elsewhere for operation and died upon the operating table. No clear history of hereditary taint could be obtained in the patient's immediate family, although the history in her husband's family was quite marked. Her husband was delicate in appearance, but did not think he had any active manifestations of tuberculous trouble. This patient had suffered from one or two abortions, from which her ill health had dated.

**Case III.**—A German housewife, aged thirty-nine, had a sister who suffered from Pott's disease. The family history in other respects seemed good. The patient had been twice married and had borne two children, who died young. About three years before presenting herself at the Woman's Hospital she had suffered from a miscarriage at three months. She dated her ill health from that period, but thought it also partly due to the fact that immediately afterward she had to go into a mill to work in order to support herself. Her menses had become irregular. Five months before I saw her she had been to another hospital, to which she had applied for treatment for abdominal distention. Paracentesis abdominis was done, and four and a half quarts of clear serous fluid removed. She came to us seeking treatment for a similar condition. Tuberculous peritonitis was diagnosed and an exploratory abdominal section made. A quantity of free fluid was evacuated. The intestines, peritoneum, and all the pelvic organs were found to be studded with minute miliary tubercles, or, as Dr. Kelly describes the appearance, "peppered with little white seeds." The uterus and appendages were glued to the wall of the pelvis and inseparable from it. There was apparently no collection of pus nor any active inflammatory process in progress. The disease had evidently assumed a chronic phase, the pelvic adhesions and the serous exude remaining to testify to the more active conditions which had preceded them. After irrigation of the peritoneal cavity the wound was closed and healed by first intention. When I last heard from the patient she was again increasing in size, and doubtless will again need to have the fluid removed.

Repeated evacuation of this ascitic fluid does sometimes, it is reported, lead to cure. Occasionally even after operation the patient develops tuberculosis of the thoracic cavity or a tubercular meningitis to which she succumbs.

A colored woman whom I saw last spring evidently suffering from ascitic distention
due to tuberculous peritonitis refused operation, and died in the early fall of rapid pulmonary phthisis. It would thus appear that operative interference afforded the one chance both of palliation and cure.

Case IV.—An American, thirty-two years of age, with extreme distention of the abdominal and irregular masses filling the pelvis. She was emaciated to a skeleton and suffered from great weakness, having been confined to her bed for two months or more before I saw her. Examination of the chest gave no evidence of lung involvement. Examination of the abdomen and pelvis under anesthesia showed the presence of free fluid in the abdominal cavity, while resistant masses were found in Douglas's cul-de-sac.

Abdominal section was done, and two and a half gallons of free fluid evacuated from the abdominal cavity. The ovaries and tubes were greatly enlarged and thickly studded with tuberculous nodules. Double salpingo-ophorectomy was done. A glass drainage-tube was introduced into the lower angle of the wound and drained as frequently as every two or three hours until the fifth day after operation. The amount of serous secretion lessening, a rubber drain was introduced and kept in place for four days longer, when it was removed. The patient made a good recovery, the wound healing. She gained flesh, and five weeks after the operation returned to her home in a distant town. Within three months after her return to her home she needed to be tapped twice, the fluid accumulating, and, soon after the last operation was performed, she died of exhaustion, as reported by her physician.

There was no history in this patient's case of hereditary tendency to tuberculosi. Though not robust she considered that she had very fair health. In a married life of seven years she had borne three children. Her youngest child had Pott's disease. Her own health had not been as good since the birth of this child. She suffered mainly, she thought, from indigestion, and complained of cutting pains in the abdomen on a level with the umbilicus. The skin around the umbilicus was very red and edematous. She was never conscious of pelvic distress and menstruated regularly and without pain. For about nine weeks previous to my first seeing her she had noticed a very marked and rapid increase in the size of her abdomen. She lost flesh and strength rapidly and was obliged to take to her bed. The peritoneum was found intensely red and thickened, due to the acute character of the inflammatory process. The primary seat of the disease and probable avenue of invasion was to be found, we thought, in the tubercular tubes and ovaries.

PRESCRIPTION FOR ANTACID POWDERS.

The Revue de Therapeutique Medico-Chirurgical of November 15, 1892, contained an article by Lyon, in which a number of prescriptions were given for the treatment of excessive acidity of the stomach. Amongst these we find the following:

Bicarbonate of sodium, 6 grains;
Prepared chalk, 2 grains.
To be made into a powder, and one of these given three times a day.

Or,

Bicarbonate of sodium, 15 grains;
Prepared chalk,
Calcined magnesia, of each 2 grains.

Should there be pain in the stomach with the acidity, it is well to prescribe a powder consisting of five parts of magnesia and fifteen parts of the subnitrate of bismuth, which is to be made into ten powders and one of these taken every hour. In other instances it is well to dissolve one of the following powders in a small glass of seltzer water:

Bicarbonate of sodium, 6 grains;
Borax, 2 grains;
Salicylate of sodium, 3 grains.

This mixture is to be taken before breakfast. After breakfast a similar powder may be taken to stop fermentation and relieve flatulence and pain.

Another prescription, which Lyon credits to Einhorn, is:

Calcined magnesia, 2 drachms;
Powdered rhubarb, 2 drachms;
Carbonate of sodium,
Bicarbonate of sodium,
Powdered sugar, of each ¼ ounce;
Essence of peppermint, enough to flavor.

A saltspoonful of this powder may be taken two hours after each meal in Vichy water.

Rosenheim prescribes the following powder:

Calcined magnesia, 90 grains;
Bicarbonate of sodium,
Powdered rhubarb, of each 1 drachm;
Extact of belladonna, 2 grains.

A saltspoonful of this may be taken three times a day in half a glass to a glass of water.

Constipation, which is so frequently a complicating symptom of this condition of acidity of the stomach, is to be combated by the use of rectal injections, abdominal massage, and rarely by laxatives. Often the administration of small doses of castor oil from time to time, a little sulphur, magnesia, and cream of tartar, would be sufficient.

Leading Articles.

DISORDERS OF THE HEART DEPENDING UPON VASCULAR CHANGES.

It is not our intention in this editorial to deal with those secondary lesions which are so frequently found in the heart muscle, associated with more or less grave pathological changes in the walls of the blood-vessels, such for example as those which are so frequently met with in persons suffering from atheroma due to syphilis or old age. It is rather our intention to deal with functional disturbances in the circulation, which are often treated by the administration of drugs acting directly upon the heart, rather than by the use of remedies designed on the one hand to overcome arterial spasm, or on the other to increase vasomotor activity and consequently produce a rise in blood-pressure.

We have long been convinced that a very large proportion of patients presenting functional cardiac disturbances suffer from a disordered vasomotor nerve condition, and that remedies directed to this portion of the circulatory apparatus are the drugs to be sought after. We therefore have read with much interest a report which is published in the Journal des Praticiens of December 10, 1898, in which the author deals particularly with palpitation and peripheral vascular constriction in anemic persons, citing a case as illustrative of the theme of his paper. He points out how disorder of the peripheral circulation often results in disturbed cardiac action, and quotes Huchard’s well known book upon diseases of the heart in support of his proposition.

In those cases in which anemia is present the cardiac disturbance is best overcome by the use of iron preparations combined with hot and cold douches alternately, to improve the vascular tone. Massage is also to be applied to the extremities, and active frictions are also of great value. It is said that in addition to these external applications the following preparation may be used as a liniment for the purpose of improving the tone of the peripheral blood-vessels:

- Spirits of juniper, 4 ounces;
- Spirits of lavender, 2 ounces;
- Essence of turpentine, 1 ounce;
- Menthol and thymol, of each 7 grains.

In those cases in which there seems to be vascular spasm, nitroglycerin in the dose of 1⁄12g of a grain three times a day is of value, or in other cases nitrite of potassium may be used. In regard to tetranirol as originally recommended by Bradbury and Broadbent of England, Huchard states that this substance possesses the advantage of being more lasting in its influence than nitroglycerin. He administers half a grain in each twenty-four hours, giving as a rule about one-tenth of a grain at a dose, usually in alcoholic solution; but we think this dose is too large.

Our own experience has been that in many instances the use of belladonna for relaxation of the vessels, or one of the nitrates if there is spasm of the vessels, combined with minute doses of aconite if there is cardiac excitement, or small doses of digitalis if there is cardiac feebleness, will produce excellent results, particularly if the patient leads a regular life, avoids the use of stimulants and tobacco, and subjects himself to gradually increasing cold in the application of cold douches morning and night.

We fear that physicians are often inclined to direct their entire attention to the condition of the heart muscle and to ignore the state of the blood-vessels, both in regard to their functional activity and their anatomical condition.
THE POSTURE OF THE HEAD IN ANESTHESIA.

The writer of this editorial has endeavored in many ways within the past few years to bring before the profession the importance of maintaining the head in a proper position during the administration of an anesthetic, and while he does not wish to be considered as a too ardent advocate of a given method, he sees this one so seldom used, and when employed so valuable, that he believes it should be more widely utilized. At the present time the erroneous idea exists in the minds of many physicians that the proper attitude of the head when breathing becomes difficult or labored is that of extension backward; and supports are taken away so as to allow the head to fall backward or beyond the edge of the table. This stretches the anterior portions of the neck and without doubt opens the glottis and draws the epiglottis away from the glottic opening. Although this movement of the epiglottis is accomplished by this method, the soft palate is strapped across the dorsum of the tongue so that no air can be taken through the mouth, and the patient is forced to breathe entirely through the nose. The nose is theoretically the organ of inhalation, but too often it is obstructed by hypertrophied turbinated bones, by polypi, or by the secretions produced in large amount by the irritant vapors of the anesthetic, and as a result the patient, if required to breathe through the nose alone, will draw air into his lungs only with the greatest difficulty. On the other hand, if the head is thrown forward and at the same time the neck extended by drawing the head of the patient, lying prone on the table, toward the anesthetist, the epiglottis is drawn away from the glottic opening more effectively than in the position of backward extension, and the soft palate is not strapped over the tongue but is, if anything, far removed from it, with the result that the patient can breathe through the mouth as well as the nose. That this position of the head and neck is the correct one to obtain the easiest access of air to the chest is proved by removing the basilar process of the occipital bone in a cadaver, when the wide opening of the glottis and the epiglottis well carried away from it can be readily seen. Further, it will be remembered that the professional runner and the trotting-horse do not extend the neck and throw the head backward when they seek to get more air into the lungs, but they extend the neck and throw the chin and head forward as far as possible. This straightens the air-passages and gives free entrance to the air.

These views were advanced nearly ten years ago by Dr. Edward Martin and the writer, and we have found in practical experience that they are correct. If this posture can be maintained as long as breathing is labored much relief will be had.

The second point of importance is that the tongue should not be drawn out and over the lower teeth, but outwards and slightly upwards. If this is done the traction is conveyed directly to the epiglottis, which is thereby removed from the glottic opening.

THE TREATMENT OF NEURALGIA.

The recollection that neuralgic pain is usually only the manifestation of some other underlying difficulty, and that careful search for and the discovery of this difficulty and its consequent removal will relieve the neuralgia, is perhaps the most important part of the treatment of this affection. At the same time, patients suffering from neuralgic pain urgently demand speedy relief, and therefore it behooves the physician to have ready for instant employment a certain class of drugs which are known to exercise a sedative influence upon nerves or nerve centers which are giving pain because of irritability.

Amongst the common causes of neuralgia, aside from those conditions which depend upon organic lesions in nerve centers, are anemia, eye-strain, what the English would call uric-acidemia, and other disorders of metabolism closely associated with a rheumatic or gouty diathesis, carious teeth, nervous exhaustion, and finally the abuse of such drugs as coffee and tobacco.

It is quite surprising how frequently the arrest of the tobacco habit in men will cause neuralgic symptoms to disappear, and on the other hand the stopping of the use of excessive quantities of coffee in women will also result in benefit. These neuralgic manifestations by no means infrequently affect other portions of the body than the head. Frequently violent abdominal neuralgia, thoracic pains, or ovarian neuralgic tenderness take the place of cephalalgia.

Among the drugs which are commonly employed for the relief of these conditions we have various combinations of the coal-tar products, such as antipyrin, phenacetine, and acetanilid, with the bromides and caffeine,
and amongst the older drugs of well known reputation the tincture of gelsemium in full doses with an active fluid extract or tincture of cannabis indica, this combination probably standing next to the coal-tar products in its ability to relieve neuralgic pain, whether it be mild in character or as severe as that met with in migraine. Then, too, it is not to be forgotten that in many cases of neuralgia, depending upon poor circulation and nervous exhaustion, full doses of nux vomica will produce valuable results, although they cannot be relied upon, when disconnected from other supporting treatment, to be of any permanent advantage. As much as fifteen to twenty minims of the tincture of nux vomica may be given two or three times a day, as soon as the patient is known to be not unduly susceptible to its influence. Another combination of remedies which is without doubt of much value in neuralgias depending upon malarial intoxication, and which also does good in neuralgic pains not arising from this cause, is the combination of a few grains of quinine with a minute dose of morphine; the only difficulty with this treatment being that the patient is apt to become addicted to the hypnotic influence of the poppy derivative. Then, again, we have another drug, which is without doubt of very great value in certain forms of neuralgic pains, particularly in the head, namely, croton chloral, which is given in five-grain pills every half-hour until twenty grains are taken, and often proves of singular service where other remedies have failed. It is a noteworthy fact that in reflex dental neuralgias it seems to be of less value than in other forms of pain affecting the distribution of the fifth nerve, and that it is practically useless in the pain of toothache. It also possesses the additional advantage that it causes a tendency to sleep, which is useful in many cases.

In old persons, with atheromatous blood-vessels and high arterial tension, who suffer from violent neuralgic pains affecting the fifth nerve, very great good can often be accomplished by the use of full doses of nitroglycerin administered simultaneously with full doses of strychnine or nux vomica. In addition to these measures local freezing of the tissue surrounding the superficial nerve, by means of ether, in an atomizer throwing a fine spray, by the use of chloride of ethyl, or by the use of ice and salt, is not to be forgotten, while in other instances a high degree of heat locally applied by means of a baked salt-bag or other warm object will be efficacious. In neuralgic pain of deep-seated nerves, massage in the neighborhood of the nerve and over its course with a round glass rod which will dip deeply down into the tissues is often very useful, particularly if an ointment containing menthol is smeared over the part to lubricate the skin and exercise the benumbing and counter-irritant influence of this derivative of peppermint; and in still other cases a continuous galvanic current of electricity will give great relief.

THE OPERATIVE TREATMENT OF CARCINOMA OF THE RECTUM.

It is instructive to note that while in countries other than Germany the excision of cancer of the rectum, particularly by Kraske's method, which implies a resection of the sacrum, has never become popularized in the sense that it is performed by practically every active surgeon—as, for instance, is the operation for removal of carcinoma of the breast—a growing confidence in the results of the operation and a wider application of it on the part of the general surgeon seem to be noticeable features of German surgical progress. In France some surgeons have even abandoned the radical operation in favor of colostomy. This is also true of England.

For the success of radical operation it is essential that diagnosis should be made comparatively early and that the surgeon should have become familiarized with an efficient operative method. This latter, and certainly most important requisite to success, is not attained except by practice, and hence in countries where the radical operation is looked upon with disfavor this attitude is likely to change slowly, since the results of the few and necessarily ill-performed operations are likely to be unfortunate.

One of the objections urged against radical operation is that it is attended with a very large operative mortality. This, however, at least in the hands of surgeons who are fairly skilled, varies from nine to thirty per cent, the average perhaps being about midway between these two figures.

A second objection to the radical operation is based upon the common conception that incontinence always results when the sphincter is partially or completely removed, or when its nerve connections are severed. As a matter of fact, fecal incontinence is far less to be dreaded than is rectal narrowing or
occlusion. The vast majority of patients who have been subjected to resection for cancer, and who have recovered, have had fairly good control over alvive evacuations, excepting during attacks of diarrhea; and by means of diet and perhaps medicine have been able not only to pursue their regular work, but to take their part in social functions, and to know in abundant time for making proper provision when the evacuation was to take place.

Wendel has records of seven cases in which the bowel was completely continent. He has just published (Deutsche Zeitschrift für Chirurgie, January, 1899) statistical studies of Küster's 126 cases of rectal carcinoma. Of these, ninety-five were subject to radical operation, twenty-five to palliative operation, and in the remainder intervention was either refused or was not called for. It is noteworthy that two cases were under twenty years old and one over eighty. It is also noteworthy that a larger number of men are recorded as over seventy years of age than are noted under forty. Küster operated in every case in which total removal was mechanically possible. In eighty-seven out of the ninety-five cases subject to radical operations, the tumor was a cylindrical-celled epithelioma. In eight cases it was a squamous epithelioma.

As to the technique of the operation, twice it was possible to seize the tumor with toothed forceps, draw it through the anus, and thoroughly extirpate it by means of scissors cuts through sound tissue.

In eighty-seven cases it was necessary to perform either amputation or resection of the rectum. This was accomplished either by the perineal method (Lisfranc), the sacral method (Kraske), or through an abdominal opening.

The perineal method was followed in forty-six of the ninety-five cases. Eight times it was possible to remove the growth without complete transverse section of the rectal wall. The sacral method was followed in forty-six cases. Resection of the gut through an abdominal opening was performed three times.

Palliative operations consisted of colostomy and scraping with a sharp spoon. This form of curettage was performed in fifteen patients. Four perished of perforative peritonitis, and one of lung embolus. The average duration of life following it was about three months, and the stenosis for the relief of which it was performed shortly recurred; hence this method of treatment should be abandoned, since at best it gives very brief relief and is attended with positive danger.

Of five colostomies, two died—one of myocarditis and the other of pneumonia. The duration of life in the remainder was undoubtedly lengthened, and the course of the cancer was much slower than if this operation had not been performed.

Of the patients subject to amputation by the perineal method, 15.8 per cent died, and 21.5 per cent were cured. The average duration of life after operation was three years and two months. The vast majority perished of recurrence. The wounds usually healed by first intention.

Of the patients subject to the operation facilitated by sacral excision, the average duration of life was two years and six and a half months. The mortality was thirty per cent, and fifteen per cent were cured. It is worthy of note that practically only those cases too extensive or too highly placed to be reached by the perineal route were subjected to this operation.

As to the general results of all forms of operation, 9 or 9¾ per cent of these cases have been free of disease from three to twelve years; seven perished of other disorders, showing no signs of recurrence for from four to eight years after operation, giving the percentage of radical cure as 16.8.

Of Kraske's eighty patients, 18.7 per cent died before being discharged from the hospital. The same percentage were still living at the time of the report, and 6.2 per cent had been for from four to eight and a half years free from recurrence.

Hochneegg, of eighty-nine patients, reports eleven as free from recurrence for from four to ten years, three as free from two to three years, and nine as free for one year.

Mikulicz, of sixty-six patients operated on since 1890, reports four as living without recurrence more than three years.

Wendel no doubt expresses Küster's views when he states that the perineal route, if it is at all practicable, is easier, safer, attended with a shorter convalescence, and followed by better rectal control than is the sacral method.

It is statistics such as these which justify the surgeon in attempting the operation, which at the best is likely to be bloody, dangerous, and difficult. The prospect of radically curing even ten per cent of cases is sufficient justification when the alternative is an absolutely certain and usually a very distressing death.
ANTISYPHILITIC TREATMENT FOR HYDROCEPHALUS.

D'Astruc has described two forms of hydrocephalus, commonly called syphilitic. The first form is of syphilitic origin, due to the arrest of development of the brain, which is dependent on the dystrophic influence of the parental disease. Under such circumstances there are found only the cerebral malformations without the active lesions of hereditary syphilis. This condition could rightly be called parasyphilitic hydrocephalus. The second form is a true syphilitic hydrocephalus, developing during the first months of life and dependent on the cerebral localization of an active hereditary disease.

The essential lesions, as shown by autopsies, consist in alteration of the ventricular ependyma and the choroid plexus. There is in these regions a marked infiltration of embryonic cells which may cause softening of the upper portion of the striate-ganglia.

Sometimes hydrocephalus is the first indication of hereditary syphilis. More often it is preceded by lesions of the skin and mucous membrane. The affection, as in non-specific hydrocephalus, may be acute, subacute, or chronic. It usually terminates fatally.

Edmond Fornier, out of 70 collected cases of hydrocephalus due to hereditary syphilis, noted that five were benefited and six cured by antisyphilitic treatment.

Audeoud (Revue Médicale de la Suisse Romande, Jan. 20, 1899) reports a case of a child born of a mother who showed the signs of syphilis and had suffered from a number of miscarriages. After treatment she carried a child to full term, which four weeks after birth exhibited corryza and other active syphilitic surface lesions such as mucous patches. The symptoms disappeared under mercury and iodides, but recurred later. When four months old, hydrocephalus was first noted and rapidly became more marked. The child suffered from nystagmus and there was a progressive loss of intelligence. Under the influence of specific treatment the symptoms rapidly improved, and in a year had entirely disappeared.

There can be little doubt that syphilis is a common cause of hydrocephalus. The disease is much more common among children of syphilitic parents than among any others. In certain families hydrocephalic children alternate with those which are in other ways obviously syphilitic, or are born after a series of miscarriages. Hydrocephalus is often associated with other marks or symptoms, and the signs of syphilis are much more frequent among hydrocephalic children than they are among those not thus afflicted; and finally, hydrocephalus is sometimes cured by specific treatment.

It is obvious that the parasyphilitic form of the affection—i.e., that not dependent upon active specific lesions, but upon the dystrophic influence of the syphilitic heredity—is not to be reached by medication, hence it would seem wise to make but a single vigorous effort to influence a hydrocephalic child of syphilitic parentage by specific treatment; this failing, to abandon a treatment which unless it accomplishes its object can work only ill. Mercury, in the form of inunctions or hypodermic injections, is the drug on which main reliance is to be placed, the iodides being also used, in full doses.

Reports on Therapeutic Progress

CUBAN MALARIAL FEVER.

At a recent meeting of the Medical Society of the County of New York M. H. Thomson said that from his experience the treatment for Cuban malarial fever which gave by far the best results consisted in the administration of fifteen grains of quinine, fifteen grains of powdered ginger, and half an ounce of paregoric, twice a day—in the forenoon and afternoon. Under this treatment the patient received an equivalent of three grains of opium each day. This plan was tried on forty-seven patients, all of them actively febrile, and eighty-four per cent severely so. Fourteen febrile patients, of whom sixty-five per cent were severe, were treated with Warburg's tincture alone as a control experiment. In twenty-two, or forty-seven per cent of the number who took the paregoric, there was a fall of temperature to normal within twenty-four hours, and it did not rise again. The treatment was continued from eleven to fourteen days, and the patients were then discharged. In ten patients, or twenty-one per cent, from thirty-six to forty-eight hours was required to reduce the temperature to normal. In three the treatment failed to control the fever. One of these, however, had a colitis, to which his continued fever seemed to be mainly due. No relapse was recorded in any patient taking the paregoric treatment after the temperature had once been reduced to normal. In five cases, or 10.5 per cent, the paregoric treatment could
not be continued because of the nausea excited. They were then given quinine and ginger alone, and they recovered, but relatively slowly. Six out of the forty-seven proved in time to be cases of mixed infection with malaria and typhoid fever. There were only two patients who showed the effect of opium; the remainder not only were not drowsy, but seemed to be aroused from their stupor by the treatment.

Of the fourteen patients treated with Warburg's tincture, in two, or fifteen per cent, the temperature was reduced in twenty-four hours. Both of these were patients who had been recently admitted, and who had been treated with quinine previously. In twelve, or forty-five per cent, the time required to break the fever varied from forty-eight hours to ten days. In seven of the cases the Warburg's tincture failed to control the fever after ten days. All of these patients recovered in about twenty-four hours under the paregoric treatment. Of the remaining thirty-nine out of one hundred, twenty-six were admitted as convalescent, and without any fever. They were all extremely anemic, and the plasmodium malaria was found in eighty per cent. They were all given the paregoric, quinine, and ginger treatment, with as good general results as in the febrile cases. In the delirious afebrile cases the paregoric seemed to act especially well. Both from the blood examinations and from the clinical features, Dr. Thomson said that it was evident that the Cuban malarial parasite belonged to the estivo-autumnal type, and that its cycle of development in the blood is very irregular as to time. This would seem to indicate that the action of quinine is only secured at certain stages of the life history of the parasite, and emphasizes the practical benefit of administering this drug at certain times. In the more or less continuous forms of malarial fever it seemed to lose much of its effect. When, therefore, the physician has to deal with an infection not having definite remissions, quinine is still valuable if given at proper times, but increasing the dose in these cases seems only to make matters worse.

For many years Thomson had been accustomed to prescribe quinine with an equal quantity of ginger, and had obtained better results in our common agues than with quinine alone. Opium had been known to be of benefit in the treatment of malarial fevers since the time of the ancient Greek and Roman physicians. In this century it has been highly praised by Dixon, of South Carolina, as a remedy for breaking the cold stage. Sir William Roberts, who served on the commission in India which investigated the method of treating malarial fevers by the use of opium, maintained that the antimalarial properties of opium were due to its alkaloid, commonly called narcotin, but which, he said, was better described as anarcotin. This alkaloid constituted a considerable proportion of the drug, varying in different samples of good opium from one-fourth to two-thirds of the percentage of morphine. Sir William O'Shaugnessy in 1838 had reported one hundred and thirty-eight cases of malarial and remittent fevers treated by opium, with ninety-five per cent of cures. This had induced the Indian authorities to institute further experiments, and as a result anarcotin was prepared in quantity and distributed to the medical depots throughout India. Sir William Roberts claimed that anarcotin was scarcely inferior to quinine, and in some classes of cases was actually superior to it. The speaker said that it was a question whether or not the beneficial action of the paregoric treatment was due to the presence of anarcotin; he was inclined to believe that the opium acted as a stimulant, thus enabling the system to cope better with malarial infection. It was because of its superior stimulating properties that he had chosen the paregoric preparation of opium. Certainly in the majority of the cases the drug acted as the reverse of a narcotic, and rather as a general cardiac and nervous stimulant.

The cases of mixed infection with typhoid fever and malaria ran the usual course of typhoid fever, and they were treated without any quinine. Two of the patients, after being fairly convalescent from the typhoid fever, had had an attack of chills and fever, which had soon yielded to the paregoric treatment. During these attacks the plasmodium had reappeared in the blood. Three of the patients died, and, strangely enough, all from an unusual cause — i.e., intestinal hemorrhage. As this accident had occurred only once in one hundred and fifty cases at the Roosevelt Hospital, its occurrence in these three cases led to close investigation of the previous history. This elicited the fact that all of these soldiers had insisted upon continuing at drill for some time after they had been taken ill. Twelve of the patients were given the artificial Nauheim baths, and twelve other patients, as nearly as possible in the same
condition, were used as a control. In every instance the effect of the cold Naunheim bath was to lower the temperature for a longer time than the simple cold bath. The stimulating cutaneous impression of the carbonic acid gas also seemed beneficial, although the nurses complained of the prickling it produced on their hands.

Nine patients were treated by intestinal lavage every afternoon, six pints of normal saline solution being administered at a time through Kemp’s irrigator. For two days before beginning this treatment careful observations were made as to the quantity of urine excreted. During the irrigation treatment the patients were given the same quantity of fluid as on the two days of preliminary observation. In seven patients the urine was increased from ten to twenty ounces daily. There could be no question that the other symptoms were also improved, so that these few observations should at least encourage one to give the treatment more extended trial. The object of the treatment was to diminish the well-known toxicity of the blood in typhoid fever.

SOME REMARKS ON ACNE ROSACEA, WITH ESPECIAL REFERENCE TO TREATMENT.

GILCHRIST, of Baltimore, writes on this subject in the Maryland Medical Journal of December 10, 1898. He divides the treatment into constitutional and local measures. In women any menstrual disorder should be corrected as far as possible, and all alcoholic stimulants should be stopped. Good, plain diet should be taken, and the patient should be told to avoid all forms of pork, pickles, salads, especially salad dressings, highly-seasoned foods, rich gravies, sauces, cheese, pastry, candies, cakes, boiled coffee, strong or long-drawn tea, and very hot liquids. The use of sugar and tobacco should not be too liberal. Fresh fruits and green vegetables are to be recommended.

For the constipation fluid extract of cascara sagrada has proved to be the most useful, and it is usually ordered to be taken at night; in some cases Hunyadi water taken in the morning is more efficacious.

Dyspeptic symptoms are often corrected by the attention to diet and the use of the laxatives. If the tongue is much coated an alkaline bitter tonic should be ordered.

Malcolm Morris speaks very highly of the use of ichthyol internally, in five-grain doses morning and evening, for the flatulent forms of dyspepsia.

This attention to diet and correction of constipation will improve the condition, but will not cure the disease, especially in its second or third stage, so that local treatment is always necessary. This consists in the use of the proper kind of soap, the application of local remedies, scarification, or the use of the electric needle.

When the skin is much thickened, and there are many acne papules and pustules, the German green soap is the best, used with hot water and a piece of white flannel every night, until the skin begins to peel consider-ably. In the less severe cases white Castile soap is very good. The writer has found five-per-cent resorcin soap (Eichooff’s) very efficacious in aiding the treatment.

The chief constituent of lotions and ointments is precipitated sulphur. Speaking generally, lotions are more applicable in the summer months or when the skin is greasy, whereas ointments are more useful in the winter. With the precipitated sulphur, which is made up with lanolin, one can use salicylic acid, two to seven per cent, when the skin is hypertrophied. Sweet almond oil should be added to give a soft consistency to the mixture (one drachm to the ounce). A prescription for an ointment would be as follows:

\[
\begin{align*}
\text{Sulphur precipitate, } & 3 \text{ j vel } 3 \text{ iv;} \\
\text{Acid salicyl, grs. } x & \text{ vel } xxx; \\
\text{Ol. amygdal. dulcis, } 3 & \text{ j;} \\
\text{Lanolin, } 3 & \text{ j.}
\end{align*}
\]

S.: Apply at night after washing.

(The salve should not be gritty, but perfectly smooth.)

As a lotion Kummerfeld’s solution, used in varying strength according to the severity of the case, will be found to be very efficacious, especially in connection with scarification:

\[
\begin{align*}
\text{Sulphur precipitate, } & 3 \text{ j to } 3 \text{ j;} \\
\text{Pulv. camph., gr. } & v; \\
\text{Pulv. tragacanth, gr. } & x; \\
\text{Aquæ calcis, } 3 & \text{ j;} \\
\text{Aquæ roseæ, } 3 & \text{ j.}
\end{align*}
\]

S.: Apply at night after washing.

Unna’s mercurial and carbolic acid plaster mulls are sometimes of much value in the early stages of the disease.

These local remedies are very good, but yet they rarely cure the disease of themselves. Scarification or the application of the electric needle is a very necessary adjunct to the treatment.

Scarification can be done in three ways:
first, by linear scarification; secondly, by slitting up the dilated cutaneous blood-vessels; thirdly, by puncturing rapidly.

The writer began this form of treatment by using the first method, which was introduced by Hebra, but soon gave it up as too unsightly, and now uses a less unattractive plan. Linear scarification consists in making a number of closely aggregated linear parallel cuts into the skin about one-sixteenth of an inch deep, and after the bleeding has been stopped by using absorbent cotton, tincture of ferric chloride is applied. This treatment results in the formation of microscopical scars and the disappearance of the dilated blood-vessels by atrophy. A scarifier is a small double-edged instrument shaped like a small arrow-head. The writer does not recommend this plan, as other less unsightly and just as efficacious methods can be adopted. The second method presents the same objection.

The third plan is the best. The writer has used this very extensively, and it is applicable in all stages of the disease, but especially when there are no very large vessels, which can be treated with the electric needle. The bleeding which ensues from the rapid puncturing is sometimes profuse, but it soon stops on applying absorbent cotton. In puncturing, the best plan is to stretch the skin and then puncture perpendicular to the surface of the skin, about one-sixteenth of an inch in depth. After a little practice one can soon puncture quite rapidly, and after a longer trial of this method it will be found that one can make nearly 500 punctures per minute, so that the nose, for example, could be scarified in about ten to fifteen seconds. This plan of treatment is carried out once or twice a week, according to the severity of the case. It will be observed very noticeably how much less severe the bleeding is as the case improves. If similar scarification is done on normal skin very little bleeding ensues—in fact, only a few drops will ooze out of the punctures.

Women, as one would suppose, bear this treatment much better than men, and they appear to stand the scarification very well.

In nervous patients one can benumb the skin by using an ether spray on the skin or ethyl chloride. This form of scarification is never followed by scars. All sebaceous plugs should be expressed, and all acne papules and pustules should be opened.

The advantage of this plan is that the patients look no worse after leaving the office than when they entered, so there is no transient disfigurement, as in the linear scarification.

Lassar has invented an electric motor attached to a puncturing machine with 100 points, which thus allows of greater rapidity of action. This method is especially efficacious for the destruction of the dilated blood-vessels. The galvanic battery is used, and the patient holds the positive pole, with a moistened sponge attached, in the hand, while the doctor uses a fine platinum needle attached to the negative pole.

The writer uses from four to eight cells of a dry silver cell battery. The needle is inserted into a blood-vessel; the circuit is made by the patient grasping the sponge, and if the needle has entered the vessel bubbles are seen to arise in it, the skin around becomes whitish, and the vessel disappears. Only a few seconds is required to produce this result. Each visible vessel is thus treated. No scars are left.

For redness alone the application of both sponges of negative and positive poles over the patch, and moving them about for fifteen to twenty minutes, produces good results. A similar strength of current is used in this method.

In summing up the treatment, this consists, then, of strict attention to diet, correction of any dyspepsia, constipation, menstrual troubles, avoiding the use of stimulants, washing the face in hot water every night, after which a sulphur ointment or lotion is applied, local treatment by scarification for the redness, and the application of the electric needle when any blood-vessels are visible.

**SUGAR AS A RATION.**

Some trials were made during last year's German autumn maneuvers regarding the value of sugar as nourishment for troops. In each of the companies directed to carry out the experiments ten men, chosen from amongst the least vigorous, were told off as the subjects for experiment, another ten being also selected who were strictly confined to the service rations. The amount of sugar supplied daily to the men was gradually increased, and their weight increased proportionately more than that of those who were without it, while the men themselves were in better health and more vigorous than they had been before. When on the march a piece of sugar relieved hunger and appeased thirst, while, thanks to it, it was found easier to fight the exhaustion produced by the heat.
No objection was made by the men to taking the sugar. The results of the experiments were considered successful, and Dr. Leistenstorfer, under whose superintendence they were carried out, has suggested that sugar should be added to the rations in one of the three following ways: (a) As a supplementary allowance, with the view of improving the men's daily ration; (b) as an integral part of the men's reserve store of provisions, and of the supplies for fortresses, hospitals, and ships; and (c) as a temporary allowance for strengthening the men and renewing their vigor on the march.—British Medical Journal, Jan. 14, 1899.

SKIN ERUPTIONS CAUSED BY ANTIPYRIN.

Wechelsmann gives a brief description of the varieties of skin eruptions met with in cases of antipyrin poisoning, and also relates the conditions which he had observed in five cases:

In a man aged thirty-six, who had suffered from attacks of migraine for several years, and had been in the habit of taking antipyrin pretty freely without medical advice, a vesicular eruption suddenly occurred round the mouth and front part of the tongue; the penis, scrotum, and anus were similarly attacked. The eruption was extremely painful. When the antipyrin was discontinued the patient soon recovered. As an experiment a small dose was again administered, and in an hour and a half the eruption reappeared.

A woman aged forty had taken antipyrin for migraine. The lips, eyelids, tongue, and dorsal aspect of both hands were attacked with a painful vesicular eruption. On inquiry she admitted having taken antipyrin for her headaches. At a later date she took a grain of antipyrin; this small dose was sufficient to cause an eruption identical in every respect to the former one.

A man aged sixty-two, suffering from diabetes, after taking antipyrin for some time, noticed a hemorrhagic eruption on the dorsal surface of his left hand; the skin was edematous. The drug was discontinued, and the eruption immediately began to subside. Pigmentation was noticed for a considerable time after the eruption had disappeared.

A diabetic man, aged sixty-six, for six years had suffered from a vesicular eruption, which occurred every second year. The parts attacked were the dorsal aspect of both hands, the lower lip, anus, and scrotum. After a short time the vesicles burst, leaving a scale which gradually died away.

A man aged twenty-nine had suffered from periodic attacks of "eczema," which one doctor had called syphilitic. In May, 1893, he took three grains of antipyrin for headache, and in half an hour he began to feel a burning sensation in the perineal region, also between the fingers and on the dorsal aspect of the hands; later the toes became affected. Vesicles formed, and the whole progress of the case coincided with his former attacks of so-called eczema. The patient was advised never to take antipyrin, and he had no further skin trouble.—British Medical Journal, Jan. 14, 1899.

THE ADMINISTRATION OF SOMATOSE.

Joachim (Pharmaceutische Zeitschrift, No. 87) has found that patients are often unable to prepare solutions of somatose. The best method of preparing it is as follows: Fill a wine-glass with cold water, and then add three teaspoonfuls of somatose, which must be sprinkled on the top of the water. The wine-glass should be moved as little as possible, so that the somatose remains on the surface of the water. After a few hours the solution is ready for use. The quantity required during the day is best prepared the evening before. The three teaspoonfuls of somatose is sufficient for the day. In the morning a third part may be taken with milk, at lunch, and later at dinner; the remainder should be mixed with soup or porter.—British Medical Journal, Jan. 14, 1899.

OIL OF GAULTHERIA IN CHOREA.

Luigi (La Riforma Medica, Nov. 28, 1898) has met with considerable success in the treatment of chorea by means of oil of gaultheria used externally. He used from six to ten grammes of the oil, either pure or mixed with vaselin, as dressing for the upper and lower limbs, alternately, the limbs being afterwards covered with oiled silk to prevent evaporation. Phenol could be detected in the urine six hours after the oil was applied. In some of the cases the drug was given internally as well. The results were very satisfactory, so that the author recommends its use, especially in cases where the other salicylates are not well tolerated. Moreover, the good effects were not confined to cases where distinctly rheumatic symptoms were present.—British Medical Journal, Jan. 14, 1899.
THE TREATMENT OF ITCHING.

In *Treatment* of December 22, 1896, Savill tells us that the treatment of general pruritus and prurigo merits very careful study, for it makes the lives of many people unbearable. He has met with two cases which resulted in insanity, and one which led to suicide. Baths and other local remedies are sometimes of use. A creolin bath, for instance (in the proportion of 1 drachm to 10 gallons), or an alkaline bath (bicarbonate of sodium 8 ounces, water at 90° F. 30 gallons). Plain warm water sometimes relieves, but not infrequently patients say that it aggravates the condition. Ointments and lotions are practically of very little use, because of the wide distribution of the trouble. A lead and zinc lotion may be tried, or preparations containing a little calamine or bismuth. Hydrocyanic acid seems to have a local sedative action, and a lotion of equal parts of liquor ammoniae acetatis, methylated spirit, and rose-water is pleasant, because it is cool. But all these measures are only palliative.

We must turn, therefore, to constitutional remedies. Hebra recommended carbolic acid internally in doses of one-half grain. Tincture of gelsemium, twenty minims given thrice daily, has been known to relieve. But perhaps the best of the internal remedies hitherto in use is chloral hydrate, ten or fifteen grains thrice daily. However, it is unfortunately attended by narcotic properties and a dangerous habit may be induced, and the moment it is left off the itching returns as badly as before. Pilocarpine internally, by promoting perspiration, is sometimes useful, as already mentioned. The bromides would theoretically be indicated here, and in cases attended with a marked neurotic element they are useful. But in ordinary cases of prurigo and pruritus, beyond the fact that they induce sleep, and help the patient to cease scratching, they are in his experience absolutely useless, though he has tried them many times.

In 1896 Dr. Savill first tried calcium chloride in large doses, the idea having occurred to him after reading Professor Wright's researches into the effect of this remedy in increasing the coagulability of the blood. The fact that cases of prurigo are frequently attended by erythematosus or urticarial exudations seemed to him to point to a tendency in the blood in such cases to exudation, and therefore to increased fluidity—that is to say, diminished coagulability. Consequently, whatever would increase the coagulability might, he thought, relieve this troublesome symptom. The favorable results attending the administration of calcium chloride in the first few cases induced him to try it more extensively, and in almost every case the effect was very striking. Seven cases were published in 1896. Since then many observers have tried the same remedy, and on all hands he has received striking confirmation of the efficacy of this remedy, not only in cases of general prurigo, but also in relieving the itching which accompanies all kinds of eruption.

THE LATEST REPORTS ON THYROID THERAPY.

With the treatment of myxedema, cretinism, Basedow's disease, lipomatosis universalis, cachexia strumpiva, and insanity, it would seem as if the use of thyroid had reached its limitations. The successful administration and beneficial results obtained in some of the above diseases, however, have stimulated many observers and experimenters to make a wider trial of this form of medication, with the result that hardly a week passes by without an attempt being recorded to extend its field of usefulness. Thus we find Hertoghe advocating the use of thyroid as a galactagogue, and his good results have been corroborated by Stawell. Apart from this, the *Klinische Therapeutische Wochenschrift*, No. 24, 1898, mentions spastic torticollis, tetany, acromegaly, Parkinson's disease combined with struma and scleroderma, as conditions in which the administration of thyroid gland has proved beneficial. Delage reports the case of a woman suffering from hemophilia, with bleeding gums, excessive menstruation, and purpura, in whom thyroid effected a complete cure. In gynecology good results have been reported from the administration of the extract in fibroid tumors, the growth having decreased in size and the general health improved. In dermatological practice the remedy has found its principal application in psoriasis and ichthyosis, although premature grayness has responded to its use.

The dosage, method of administration, and danger-signals are no less important than the indications for its use. The hypodermic administration of the liquid extract and the grafting of the fresh gland have long fallen into disuse, and the tendency of the present day is to administer the powder or to give tablets or capsules prepared from the desiccated fresh gland. The dose varies with the
THE SURGERY OF THE POSTERIOR MEDIASTINUM.

The mediastinal spaces are among the territories most recently conquered by the advancing army of surgeons. Their invasion has, however, been quite gradual. Both Hippocrates and Galen make mention of procedures to be employed in dealing with intrathoracic disease, but it is only within the antiseptic era that any real advance has been made. The simple operation of thoracotomy, which was then in high disfavor, was in 1841 made the subject of an appreciation and approval by Sedillot; but until Moutard-Martin reintroduced the operation in 1872 no general adoption of it can be recorded. Since then, however, it has leaped into general favor, and now it is one of the simplest and most frequent of operations. Emboldened by its success, several operators—Estlander, Letiévant, Schede, and others—suggested and carried out a wide extension of its principle, and the method of thoracoplasty became, through their endeavor and example, a classical operation. But more than this resulted. By multiplying experience it began to be recognized that the pleural sac has been held quite unnecessarily in dread. It was seen that much freer interference with it could be safely tolerated. By experiments upon animals Glück and Schmidt showed that the healthy lung was capable of being removed wholly or in part; and Biondi, after artificially producing tuberculosis of the lungs, dealt with the affected portion by complete removal. In 1885 Omboni fulfilled expectation by showing that wounds of the human lung could be treated by immediate suture with success, and the possible surgical achievements in this direction received their final completion by the successes of Tuffier, Lowson, and Doyen in the operation for removal of diseased human lung.

That other organs lying within the chest might be brought within the reach of the surgeon’s knife was first demonstrated by Nasiloff, of St. Petersburg, who in 1888 made a series of investigations on the cadaver. Conclusions very similar to his were arrived at by Quénu and Hartmann in 1891. These three observers had all agreed that the shortest and best method of reaching the esophagus as it lay within the chest was by means of an incision to the left of the vertebral column. Portions of three, four, five, or more ribs were resected and the pleura stripped up. Potarca in 1893, and again more recently, advocated, as a result of many

THE TREATMENT OF OBSTINATE CONSTITUTION BY MASSAGE APPLIED TO THE HYPOCHONDRIUM.

Berne has reported the treatment of this class of patients by massage applied exclusively to the region of the gall-bladder, just below the diaphragm, for the purpose of increasing the flow of bile and improving the activity of the abdominal contents. This method is particularly useful in those cases where there is relaxation of the abdominal wall and a general tendency to enteropositis. It is well, however, not to employ this treatment should there be any possibility that the patient is suffering from gall-stone, since massage might produce a cholecystitis.

The operator passes the tips of his fingers and the ball of the thumb over the soft tissues immediately below the ribs, following the line of the lowest rib, making continuous and deep pressure, the patient lying on the back with the knees drawn up and taking a full inspiration so as to push the liver down under the operating hand. The massage lasts for about ten minutes each day, and it is stated that ten or twelve treatments are usually efficacious, but the treatment should be continued for thirty or forty days if the result is to be lasting.

As a proof that this treatment increases the flow of bile into the intestine, we find that the stools become less fetid, contain a greater quantity of bile, and that the constipation is decreased.—*Revue de Thérapeu- tique Médico-Chirurgical*, Dec. 1, 1898.
observations made on the cadaver, and by experiments upon dogs, that the shortest and most advantageous route to the posterior mediastinum and the esophagus lay through an incision to the right of the middle line. Other contributions were made to the subject by Ziembicki and Bryant, but the best, the fullest, and most complete account was furnished by Obalinski in 1896. This author related five cases of suppurative posterior mediastinitis treated by Nasiloff’s method, with subsequent drainage, which had been under his own observation in Rydygier’s clinic, and recorded eight others observed by Morian, Ziembicki, and Kryniski. Of the thirteen cases, three were acute, ten chronic. The latter were dependent upon tuberculous disease of the dorsal vertebrae. The results were, on the whole, satisfactory.

The most recent contribution to this subject appears in the last number of the Archiv für Klinische Chirurgie from the pen of Professor Rehn, of Frankfurt. Two cases are recorded—one of cicatricial contraction of the esophagus, the result of swallowing some caustic fluid in an attempt to commit suicide by a young man aged twenty-two; and the other a case of malignant stricture of the esophagus in a man aged forty-nine. In the former the esophagus was exposed by a curved incision on the right side of the dorsal vertebrae, and the removal of portions of the fourth to eighth ribs. The pleura and the lung were easily drawn away. A sound in the esophagus showed the site of the stricture. A longitudinal incision was made through the stricture, the sound passed on into the stomach, and the esophageal wound stitched over the sound. In the second case a large growth in the esophagus was everywhere adherent. The pleura was wounded. Both patients died—the former after a prolonged illness, during which he became progressively exhausted; and the latter after six days of cardiac failure, due, as shown by post-mortem examination, to old-standing pericarditis and myocarditis.

These operations of Obalinski and Rehn prove, then, that it is physically possible, without wound of any important viscus, to reach the esophagus as it lies within the chest. It is therefore the question of early diagnosis which requires further elucidation. It may be that in esophagoscopy lies our means of solving this difficulty. Good work has already been done in this direction by Mikulicz, Rosenheim, von Hacker, and others, and a more extended use of the method may enable us to recognize in their early stage the exact causes of esophageal obstruction. It seems not improbable that in a case of malignant disease diagnosed early and treated in some such manner as that adopted by Rehn, a successful resection of the diseased portion of the esophagus may in the near future be recorded. As yet, however, the subject is merely one of promise unfulfilled.—British Medical Journal, Jan. 7, 1899.

TREATMENT OF ASTHMA.

Goldschmidt (Munich, 1898) closes an essay on this subject with a consideration of the treatment of the affection. He divides it into (1) purely medicinal, (2) the physical, and (3) the inhalation treatment. He attaches great value to the use of morphine in some cases, especially where the attacks are infrequent but pronounced. If morphine is not well borne, then chloral may be used in a dose of two grammes, to be repeated in doses of 0.5 gramme every quarter of an hour until sleep is induced. More than five grammes should not be given in this way. In cases of prolonged asthma with expectoration, iodides combined with expectorants and opium are often useful. Amyl hydrate also acts extremely well, but sulphonal and trional are useless. Stramonium fumigation may be of great value, but sometimes fails. Occasionally antipyrin and quinine may be useful. The attacks return after the chloroform narcosis passes off. Expectoration must be encouraged, and here the iodides are of most service; they may be given over long periods of time. In cases where expectoration is abundant iodides may not only be useless but harmful.

Goldschmidt then discusses the value of the compressed air cabinet. This is useful in some of the sequelae of asthma, but not in the actual acute attack, which may indeed be made worse by it. Inhalations are far too little appreciated in asthma. Irritating inhalations which produce cough must be avoided. The author attaches some value to hydrotherapeutic treatment in some cases of asthma. The patient should gradually be accustomed to colder baths of short duration with douches. Even when catarrhal symptoms are present the body may be vigorously sponged with water at 18° C. Warm drinks should be given at the same time. In some cases of permanent asthma baths at 27° C. with douches at 12° C. may be of service. When these fail vapor baths may be of great
value, but they are sometimes followed by untoward symptoms; they should be limited to two in the week. Finally, in case of an acute attack or an exacerbation the treatment is begun with stramonium fumigation. If this fails, strong stimulation of the skin with hot water should be tried. If these measures have previously been ineffective, morphine or chloral should be given.—British Medical Journal, Jan. 7, 1899.

THE TREATMENT OF TETANUS BY THE INTRACEREBRAL INJECTION OF ANTITOXIN.

The British Medical Journal of January 7, 1899, contains an article by Semple upon this topic. The details of the operation are as follows: The patient is given an anesthetic, the hair is shaved off over the forepart of the scalp, and the skin made aseptic. An imaginary line is taken over the head from one auditory meatus to the other. Another line is taken from the base of the nose to cross the first line at right angles on the top of the head, and a third line from the outer angle of the orbit to where the first two lines cross each other. The center of the last line is the seat of operation, and is in front of the motor areas of the brain.

Having selected this site, an incision of about half or three-quarters of an inch in length is made down to the bone. A small hole is now drilled through the bone with an Archimedean drill having a movable collar, so as to regulate the depth to which it penetrates. The hole in the bone need only be a little larger than the needle of the syringe, which is to be inserted through it.

The syringe has a screw piston and the needle is attached by about three inches of rubber tubing. The needle is about two inches in length, and has a rounded point. It is inserted through the hole drilled in the bone, straight into the brain substance as deep as it will go, and an assistant holds it perfectly steady while the operator very slowly screws down the piston, so as to allow the antitoxin to soak into the substance of the brain drop by drop, to avoid breaking up any brain tissue. It should take at least ten minutes to inject 3½ cubic centimeters. When this amount has been injected the needle is withdrawn, the edges of the scalp wound are drawn together by two or three stitches, and the wound sealed up with collodion and cotton-wool. The same operation is now repeated on the other side.

The object of using a round-pointed needle is to avoid puncturing a vessel. A sharp-pointed needle might possibly transfix an artery and produce hemorrhage, whereas a round-pointed one would glide off a vessel and go past it.

The antitoxin used is double the strength of ordinary antitoxin, and although only five cubic centimeters is given (2½ cubic centimeters on each side), it represents the amount of antitoxin present in ten cubic centimeters of the original serum.

The dried antitoxin from ten cubic centimeters of the ordinary antitetanic serum is put up aseptically in glass tubes, and sent out from the Pasteur Institute, Paris, ready to be dissolved. The tube containing the dried antitoxin should be opened without contamination, then five cubic centimeters of sterile water added to dissolve it. When the antitoxin is in complete solution it is filled into a sterile syringe of the pattern described (Roux's pattern, five-cubic-centimeter syringe), and is now ready for use.

In addition to the antitoxin given intracerebrally, the patient receives twenty cubic centimeters daily for two, three, or four days, according to circumstances. The antitoxin given intracerebrally immunizes the higher nerve centers before the toxin has been fixed there. The antitoxin given hypodermically renders the blood antitoxic, and the toxin as it becomes absorbed from the source of supply—wound, bruise, abrasion, or any other source, wherever it may be—is neutralized as soon as it enters the blood-stream.

The advantage of giving the antitoxin hypodermically in addition to intracerebrally is evident when we reflect that the tetanus bacilli may still be cultivating themselves, and toxin still being absorbed.

CALOMEL IN TYPHOID FEVER.

Andievsky (La Semaine Médicale, Dec. 28, 1898) has made in the Russian military hospital of Krasnoie-Sielo a series of therapeutic experiments with the object of determining the value of calomel in typhoid fever. In seventy-one cases he gave calomel in a dose of thirty centigrammes thrice daily, while for the purpose of comparison he gave quinine in the same doses in forty other cases. The patients in the first group continued to take the calomel till their evening temperature became normal; this result was obtained after a total amount of the drug varying from eight to twenty grammes had been
taken. Stomatitis never occurred, nor was diarrhea aggravated; moreover, the disease in all these patients was mild in type, and often aborted. The fever abated more quickly and the mortality (2.82 per cent) was less than in the cases treated with quinine. No patient who was out on the calomel treatment within the first week of the illness died. Andrievsky concludes that although calomel is not a specific, it is a most useful remedy in typhoid fever.—*British Medical Journal*, Jan. 7, 1899.

**ON THE CAUSE OF SO-CALLED PHOSPHORUS NECROSIS OF THE JAW IN MATCH-WORKERS.**

Stockman, of Glasgow, contributes to the *British Medical Journal* of January 7, 1899, an article dealing with phosphorus necrosis. In every case he examined the pus was very fetid and was greenish, or brownish, or grayish in color. Attempts to make cultivations from the pus revealed the presence of staphylococcus albus, streptococci, and numerous other organisms, none of which could reasonably be regarded as the cause of the cario-necrosis.

It is well known that tubercle bacilli cannot be cultivated from pus, but on staining cover-glass preparations of the pus by the Ziehl-Neelsen method the bacillus tuberculosis was found in every case. As is usual in the discharge from tuberculous bone, the organisms were few in number and difficult to find, except on the closest and most careful examination. On centrifugalizing the pus and then examining the sediment they were more easily detected. Sometimes several cover-glasses had to be examined before any of the organisms were seen. Most of the bacilli were perfectly typical in appearance, others were small and thick, resembling the form usually found in the urine. They were scattered about singly or in small clumps, or in groups of one or several dozens.

Inoculation of guinea-pigs with the pus did not infect these animals with tubercle, and hence the bacilli must be regarded as being either dead or as having almost entirely lost their infective virulence. It is now proved, however, that tubercle bacilli in this condition are quite capable of setting up and maintaining local suppuration and irritation for an indefinite time. Besides, they are assisted by the action of the pyogenic organisms with which the pus swarms. The condition of the tubercle bacilli is probably to be explained by the fact that all the cases which Dr. Stockman has had an opportunity of examining are recovering, and have been under treatment for very long periods with antiseptic mouth-washes, etc. The condition generally is exactly similar to what is seen in tuberculosis of the jaw in cattle and in tuberculous disease of other bones in man. The presence of the tubercle bacillus can hardly be regarded as fortuitous, seeing that it was found in every case, and its presence is held, so far as our present knowledge goes at least, to be proof positive of the tuberculous origin of any lesion.

If further proof of the tuberculous nature of the jaw disease were wanted, it is to be found in looking through the accounts of post-mortem examinations of fatal cases. In most cases death occurs from tuberculosis of the lungs. Whether this is due to infection from the jaw tubercle, or whether the phosphorus fumes damage the lungs, and make them more susceptible to direct infection, Dr. Stockman is unable to say.

General tuberculosis is also not uncommon, while tubercle of the abdominal glands and tuberculous ulcers of the intestine are almost invariable, these last arising certainly from infection by swallowing the pus. Abscess in the brain, purulent pleurisy, and tuberculous meningitis are also occasional causes of death. Hectic fever and emaciation always accompany fatal cases.

The part which the phosphorus plays in the process is not far to seek. The acid fumes (phosphorous and phosphoric acids) produced by its oxidation in the air have no effect on bone covered by gum or mucous membrane; but when they can penetrate to the bone directly through the aperture left by a decayed or extracted tooth, or any injury, they erode the bone, weaken its nutrition and resisting power at this small spot, and make it susceptible to infection by tubercle bacilli. The bacilli, having made good their foothold, spread slowly in some cases and with disastrous rapidity in others. Dr. Stockman says he thinks he is correct in saying that the great majority of workers in match factories have carious teeth, and yet only a very small portion of them become affected with cario-necrosis of the jaw—namely, those of them who, owing to their home surroundings or to individual predisposition, become readily infected by the tubercle bacillus. V. Bibra and Geist state that the disease may occur weeks or months after the patient has left the match factory,
and in one of their reported cases the woman had actually been eighteen months away from the work before any symptoms began. This in itself is almost complete proof that the phosphorus fumes are only a predisposing cause, and that the disease depends on subsequent infection. It is well known that V. Bibra and Geist, and later Wegner, produced suppuration and cario-necrosis in the jaws of rabbits by injuring the periosteum and then exposing the animals to phosphorus fumes (on uninjured rabbits the fumes had no effect). The rabbits all died in from five to ten weeks' time, and were found to have tubercle of the lungs. Dr. Stockman experimented in a different way, as it is evident that these animals had become rapidly infected from laboratory cages in which they were kept. He got new wooden hutches made, placed them in a room where animals had not been previously housed, and kept them scrupulously clean. In the hutches pieces of phosphorus were placed in a mortar on damp earth (to avoid risk of fire) in such quantity that the cages were constantly filled with the fumes in much greater amount than could possibly occur in any factory. Four rabbits were then placed in the hutches after the periosteum and gum had been removed over a considerable portion of the upper and lower jaws in each. In one a tooth was loosened in addition, the operations being all performed under chloroform. They seemed to suffer no inconvenience either from the operation or from living in the phosphorus-fume atmosphere. It has been very difficult to prevent the gum growing over the exposed bone, and after many weeks there is not the slightest trace of any jaw affection. The exposed surface of bone has become slightly eroded and rough, but whether from the action of the acid fumes or from that of the bacilli of the mouth it is impossible to decide.

The treatment hitherto pursued in cases of phosphorus jaw has been to wash out the mouth with deodorant and antiseptic lotions, and wait until the necrosed pieces of bone come away. This is always extremely tedious, and may last many years. In extreme cases the whole lower jaw, or half of it, or parts of the upper jaw, have been excised. Sometimes by so doing the whole of the infected portion may be removed, but frequently the disease has again broken out in a neighboring part of the bone. It is evident, however, that early operative interference is called for, and that the original tuberculous focus at the root of the tooth should be removed at once.

As regards prophylaxis, there is absolutely no risk so long as the bone remains protected by gum, and even when carious teeth are present the entrance of the bacilli can be prevented by careful stopping. Efficient ventilation of the workshops will dilute the acid fumes arising from the phosphorus, and make them less active in injuring exposed bone. The infection with the tubercle bacillus is a matter quite apart from the factories and cannot be controlled either by State regulations or workshop rules. It is acquired—as other tuberculous affections are acquired—by certain persons and not by others, and owing to the present all-pervading frequency of the organism persons with exposed bone eroded by acid fumes, and living under bad hygienic conditions, are very apt to become infected. Whether the fumes also weaken the mucous membrane of the lung alveoli and predispose to pulmonary phthisis among persons employed in match factories, Dr. Stockman says he has no information which will enable him to decide. It is just possible that actinomycoses or other organisms may also occasionally lodge in the weakened bone, and lead to caries and necrosis, but in those cases which he has hitherto examined he has only found the tubercle bacillus.

**THE SALINE TREATMENT OF DYSENTERY.**

In the *Indian Medical Gazette* for December, 1898, is an article on this subject by Buchanahan, of the British army. He thinks that diet is of the utmost importance. Boiled milk (one pint) and sago (eight ounces), soup from goat's flesh, or mutton broth, are also useful. This low diet was rigorously enforced till the stools had become solid. On the first sign of a relapse (*i.e.*, a recurrence of blood or mucus in the stools), a return was at once made to sago and milk. Stimulants were given when necessary, and general treatment ordered for certain cases which were suffering from anemia, swollen gums, or other evidences of previous malarial attack. A return was made to full diet as soon as possible to check loss of weight.

The above statement and detailed cases show clearly the rapid and beneficial action of magnesium in acute cases of dysentery. In mild cases Dr. Buchanan says he is well aware many other drugs act admirably—e.g., castor oil emulsion (according to Dr. Birch's formula) is often given, and has been very successfully used in Dacca Jail under Dr. R.
Macrae's direction. Dr. Buchanan has often used it, but it does not cure so rapidly as the magnesium. Cinnamon powder has been much recommended and acts fairly well in mild cases, but slowly in acute cases. Judging from remarks in the British Medical Journal, he thinks there is much misconception as to the use of perchloride of mercury and cannabis indica. In his experience he has found this mixture useless in acute attacks or in acute exacerbations of chronic attacks, but it has its value in the frothy fermenting stools of chronic cases, though now he prefers magnesium. There seems to be a turn of the tide against time-honored ipecacuanha (and he confesses to using it less than he used to do), but he is perfectly convinced as to its value in acute attacks of dysentery, and has over and over again proved its value and certainty. In mild cases it is not necessary, in chronic cases it is of doubtful value and safety, but in athenic acute cases it acts "like magic." In fact, he says the only drug he knows which besides magnesium will produce such a wonderful change in the stools in twenty-four hours is ipecacuanha, which has now stood the test of half a century (introduced by Scott-Docker in 1848). That magnesium can do so is clear from his cases. A patient will be passing dozens of "meat-washing" stools, with pain, gripping, and tenesmus, yet on giving him magnesium in twenty-four or thirty-six hours the stools will be entirely free from inflammatory products and be passed with comfort and ease. As Dr. Wyatt-Smith has said, it can act "like magic." The change is just as remarkable as in what a couple of decades ago writers used to call the "ipecacuanha stool."

Rationale of the Treatment.—Though to the lay mind it seems strange to treat a "bloody flux" by a purgative, yet time gives proof of the paradox. Buchanan conceives magnesium sulphate to act simply by washing out the great intestine, so removing the causes of the inflammation and the inflammatory products. According to Professor Hay, a saturated solution of magnesium produces copious intestinal secretion. The large amount of intestinal secretion in fact acts like an enema ab interno.

The drug is best given, he believes, in one-drachm or two-drachm doses every one or two hours (i.e., one to two drachms of the above quoted mixture) of a saturated solution. For all very acute cases and all exacerbations of the chronic form, Buchanan at one time recommended it, but it is obvious that to thus give small doses every one or two hours needs better and more skilled nursing than is available in prison or in regimental native hospitals. Hence, as may be seen from his cases, he has used with safety and success much larger doses at a time. One ounce of a saturated solution twice a day, half an ounce four times a day, or two drachms eight times a day, mean the same amount of the magnesium. He believes, however, that the smaller frequently repeated doses are the surest.

When to Stop the Drug.—It is necessary to secure free, gentle purgation. Dr. Buchanan finds that, as long as the stools remain yellow and loose or soft, the drug should be continued for one or two days after the mucus and blood have entirely disappeared. The quantity may be reduced. As soon, however, as the stools become thin and watery, the drug should be stopped at once. It is surprising how soon after this the stools become soft and solid. He would, however, impress upon medical subordinates that for the successful use of this drug the stools must be seen once a day or oftener. In no other way can the effect of the drug be watched, and in no other way can we know when to stop it. Stools containing sloughs should be washed in a white dish or in a tin painted white inside.

The frequent occurrence of green stools or tarry black stools was noted in his cases. The green color Dr. Buchanan says he does not understand. He has read of it in cases of yellow fever.

While thus strongly recommending magnesium sulphate in the treatment of acute dysentery, he is not to be understood as saying that it will act thus promptly and efficiently in chronic relapsing cases, but he is strongly inclined to believe that if all cases are from the first treated in this way, and care is taken not to discharge them from hospital till every trace of mucus has for several days disappeared from the stools, the chronic form will become much less frequent, except in those cases which occur as the terminal episode in malarial or tubercular cachexias. Another point: of all diseases there is none with a greater tendency to relapse than dysentery, and once a man has had dysentery very slight causes (chills, errors of diet, etc.) will bring on another attack, and such cases, if neglected, rapidly run into the intractable chronic form. Buchanan has lately started treating all chronic cases as follows: Santonin five grains (if there is any suspicion of entozoa), mag-
nesium in small doses for all exacerbations, and in the intervals olive oil in two- or four-drachm doses in milk, twice a day. This with a pure milk diet and infinite patience will, he believes, be as good a method of treatment as is known for these very serious cases. When one has to treat dysentery in a jail or in a regiment with the same patients in one’s charge for years, one realizes more forcibly than is possible in public hospital practice the essentially relapsing nature of this protein disease.

DERMATITIS AND OTHER TOXIC EFFECTS PRODUCED BY BORIC ACID AND BORAX.

The London *Lancet* of January 7, 1899, contains an article by WILD, of Manchester, upon this subject. He recalls the fact that a number of cases have now been recorded showing the occasional toxic effects of boric acid externally applied or injected into the cavities of the body. The following instances may be referred to as illustrating the different ways in which intoxication may be produced. Moledenkov reports two cases, in one of which a pleural cavity and in the other a lumbar abscess cavity were washed out for an hour with a large quantity of a solution (five-per-cent) of boric acid. The next evening erythema appeared on the face and spread to the neck, trunk, and thighs. Both patients died—one on the fourth day and the other on the fifth day. Bruzelius reports a case in which a wide-spread erythema appeared after a few days’ use of two pints of a solution (four-per-cent) of boric acid, which had been injected into the rectum in a case of chronic diarrhea, in which the patient recovered. Johnson reports a similar case, in which the injection of 36 grammes of boric acid was followed by headache, fever, injection of the conjunctive, and an erythematous, papular, and bullous eruption on the skin. The drug was easily detected in the urine. Hogner reports three cases of intoxication following the use of boric acid solution for washing out the stomach. There was general depression with an erysipelas eruption on the face, purpuric spots on the body, vomiting, diarrhea, and blood in the urine; death resulted in one of the cases. Welch records cases following the use of vaginal tampons of boric acid in which were present formation and burning of the skin (chiefly of the face, hands, and feet), severe depression, and afterwards desquamation. In these cases the patients recovered. Lemoine met with a case of intoxication after dressing a bed-sore with boric acid. Dr. Arthur Hall reports a case of extensive burns treated by boric acid ointment in which on the fifth day an erythematous eruption appeared and affected the limbs, the trunk, and the face. The patient died on the ninth day, and a necropsy revealed no organic cause for death.

Cases of intoxication following the internal administration of boric acid are fewer in number, but Corlett saw six cases when treating diphtheria with one-drachm doses of the drug. Poisoning by borax is most frequently due to its internal use for long periods in the treatment of epilepsy. Three cases of psoriasis following this use of borax are reported by Gowers, and the observation is confirmed by Liveing. Stillé confirms the observation of Binswanger already referred to regarding the production of an impetiginous eruption on the skin. Ch. Féré and Lamy report two cases of an eczematous eruption caused by the internal administration of borax, with a photograph of one case. Dr. Féré gives an exceedingly full account of his observations upon epileptic patients treated by borax. He found that in some cases intestinal irritation, nausea, and vomiting were produced. The skin and mucous membranes were dried, the lips were fissured, the hairs became dry and fell out, and the nails were often striated. On ceasing the drug the hair again grew and became thick. Psoriasis might appear, but a special form of eruption was more common, resembling in some points the seborrhic form of eczema. Papules and little red-bordered circles first appeared; they became scaly, enlarged, and ran together to form extensive patches, often symmetrical. The scalp, the arms and the hands, the flanks, and the lower parts of the abdomen were most frequently affected, but the eruption might become general. In other cases the eruption was more scarlatiniform and the desquamation finer; petechiae might be present, or in other cases furunculi. Edema of the extremities was frequently found, sometimes of the face as well, and albumen might be present in the urine. When extensive tracts of skin were affected there was a cachectic state and loss of flesh. The onset of uremia in renal cases was hastened by the ingestion of borax. The drug could be readily found in the urine, and was detected in from twenty-five to thirty minutes after a dose of four.
grammes of borax; in one patient who had taken ten grammes per day for some time it was still present in the urine forty-one days after the last dose, and in another case it was found fifty-three days after cessation of the drug. Both these cases had albumen in the urine.

Dr. Wild says his attention was first directed to the toxic effects of boric acid by the case of a man, aged thirty-eight years, of somewhat alcoholic habits, who had never suffered from eczema or psoriasis. At twelve years of age he had a severe attack of scarlet fever, at the age of sixteen years he had acute rheumatism, and at eighteen years of age gonorrhea and syphilis, for which he was properly treated, and after a mild attack of secondaries he had no further syphilitic manifestations. He contracted gonorrhea several times, and about twelve years previously to his seeing the patient symptoms of stricture of the urethra appeared and were treated, so that for some years he suffered little inconvenience. In 1896, however, the stricture became troublesome and micturition was difficult, painful, and frequent, and the urine was offensive and alkaline and contained pus. About the middle of March, 1896, he commenced to take boric acid (ten grains three times a day), and the condition of the urine improved. Early in May he noticed that the hair on his head was falling out and that the scalp was red and scaly. The hands and forearms became red, slightly swollen, and presented scaly patches on the flexor surfaces. In this condition Dr. Wild first saw him. He considered the case one of seborrhoeic dermatitis presenting some unusual features. As the urine was then clear, contained no pus, and only a small quantity of albumen, the boric acid was discontinued, though at that time there was no suspicion that the drug had any relation to the skin disease. Ordinary local treatment was adopted, and he very soon improved and was well in July; but in August the bladder symptoms were again troublesome, and he recommenced taking boric acid as before. At the beginning of September the skin eruption reappeared in a more severe form, and by the end of the month it involved the scalp, the trunk, and all the limbs. The affected skin was of a bright-red color and covered with profuse scales of a slightly greasy character. The patches of disease were irregular in shape, roughly symmetrical in distribution, and very extensive in area, leaving smaller patches of healthy skin on the trunk and the proximal parts of the limbs. The hands and forearms and the feet and legs below the knees were uniformly red, scaly, swollen, and they pitted on pressure. Desquamation on the palms and soles occurred in large flakes. The scalp was red and scaly, the hair had almost entirely disappeared from the head, and was very thin on the face and pubes. The face presented only a few scaly papules. Digestion was disturbed, the appetite was poor, and there was marked debility and anemia with loss of flesh. The coincidence of the outbreak with the resumption of the boric acid led him to suspect the drug being the cause of the eruption, especially as the symptoms agreed closely with those described by Fére in patients taking borax. The administration of boric acid was stopped immediately, and a mild sedative ointment was prescribed for the skin; improvement was rapid, and by Christmas he was practically well and had a good crop of healthy hair growing on the scalp. He remained well until May, 1897, when the bladder symptoms were again troublesome, and led him to resort to the boric acid, which undoubtedly gave him relief. In June the eruption on the skin again appeared, but to a much less extent, as he stopped the drug on the first outbreak of dermatitis. In July he was fairly well, but in August he gave way to alcoholic excess, developed uremic symptoms, and died comatose. Whether he took any boric acid in July or August is not known, but the observations of Fére as to the influence of borax in hastening the onset of uremia in patients with renal disease are particularly interesting in this connection. In this case there were three distinct attacks of dermatitis, each one occurring a few weeks after commencing to take boric acid. The chief features of each attack were a diffuse, wide-spread, scaly eruption, edema of the extremities, loss of hair, anemia, and loss of flesh, and recovery always occurred under simple treatment when the drug was discontinued. The diagnosis rested between the toxic effects of boric acid, seborrhoeic dermatitis, pityriasis rubra, psoriasis, and syphilis; and a careful consideration was given to each of these diseases before the diagnosis of boric acid intoxication was made.

By the kindness of Dr. J. S. Bury, Dr. Wild says he was recently enabled to examine a man aged fifty years, who had suffered from epilepsy for over twenty years. In June, 1898, he commenced to take a mix-
ture containing ten grains of boric acid and fifteen grains of borax three times a day. Early in August the hands began to swell, and they became red and painful and desquamated; the feet, the head, and the body were successively affected in a similar manner. On examination there was edema of the forearms and hands, also of the legs and feet, and the skin was red and scaling freely. The thighs and the lower part of the trunk presented red scaly patches, at the periphery of which minute discrete red papules could be seen. The scalp was red and scaly and bald on the crown, and the hair which remained was very thin. There were a few scaly patches and pustules on the face. Several boils were found on the thighs, the genitals, and the shoulders. There was no history of any form of skin disease before taking the boric acid and borax.

During the past year Dr. Wild has administered boric acid to nearly forty patients who were likely to derive benefit from the drug, and he has carefully watched the cases. In no case has any bad effect followed, though one patient has taken the drug continuously for four months. In one case, that of a man seventy years of age, who took eighty grains of boric acid per day in divided doses for four weeks, there was a distinct flushing and redness of the skin, with the appearance of slight albuminuria. The urine was normal before taking the boric acid, and the albumen disappeared about two weeks after it was discontinued. He says he has taken boric acid himself in fifteen-grain doses without any inconvenience. On one occasion he took 120 grains within four hours. The result was nausea, but no vomiting, and colicky pains in the abdomen, followed by diarrhea seven hours after the first dose, which continued during the night and the following morning. On the next day he suffered from slight headache, a feeling of depression, a want of appetite, and a marked flushing of the skin. The urine was increased, and sixty ounces was passed in the twenty-four hours following the first dose. It contained free boric acid, which was present in that which was first passed four hours after taking the drug, and could still be found twenty-six hours after, but it could not be detected forty-four hours after the administration. A portion of the urine was evaporated to dryness and incinerated, the ash being repeatedly extracted by ninety-per-cent alcohol until there was no green tinge in the flame when the alcohol was ignited. The residue was again ignited, acidified by sulphuric acid, and mixed with alcohol, and on igniting the alcohol, a green flame was at once produced. From these experiments he concludes that while a great part of the boric acid is excreted unchanged, a certain portion is converted into borates (probably sodium) and excreted in that form. He was unable to make a quantitative determination, owing to the fact that as boric acid volatilizes in the presence of steam a large part was lost in the process of evaporating the urine.

Experiments upon animals have been performed by J. Neumann, who found that dogs weighing fifteen kilogrammes could tolerate from five to six grammes of boric acid without other injury than fall of temperature, but larger doses caused in addition vomiting and diarrhea. Quantities up to four grammes were injected into the pleural and peritoneal cavities in a three-per-cent solution without causing inflammation; a five-per-cent solution, however, excited peritonitis. Large doses (ten grammes or more) caused death through nerve and muscle paralysis. Rabbits, pigs, horses, and fowls gave similar results.

From a review of the recorded cases of intoxication from the use of boric acid and borax, it seems clear that two forms must be distinguished—one in which a large quantity of the drug is rapidly absorbed from the alimentary canal, from a serious or other cavity, or from an extensive raw surface; in these cases vomiting and diarrhea, general depression, and partial paralysis of the nervous and muscular systems occur and may cause death. A rash is noted in many cases, especially where the patient recovered or lived some days after the absorption of the drug. The other class of cases results from the administration of boric acid or borax in comparatively small doses for long periods, and the symptoms appear at a variable time after the commencement of the drug. In some of these cases it is mentioned that the kidneys were diseased, in other cases albumen appeared in the urine, and in several cases ending fatally uremic symptoms are described. Whether the condition of the kidneys or an individual idiosyncrasy in regard to the drug is the determining factor in causing toxic symptoms requires further investigation, but it is an important fact that the great majority of persons taking boric acid or borax do so without any injurious consequences. The very rapid elimination of boric acid by healthy kidneys may perhaps explain this immunity.
REPORTS ON THERAPEUTIC PROGRESS.

It is possible that cases of intoxication occur more frequently than is at present recognized. Boric acid may be taken in food without the knowledge of the patient or the medical attendant, and a case of toxic skin eruption resembling eczema, psoriasis, or exfoliative dermatitis may easily be put down as an unusual form of one of these diseases. About four years ago Dr. Wild saw a patient—a female nearly sixty years of age—with extensive desquamative dermatitis affecting the scalp, the limbs, and the lower part of the body, with edema of the legs and the arms. She died in three weeks, and the diagnosis of seborrhoeic eczema, though appearing most likely from the character of the eruption, was unsatisfactory in view of the edema and the fatal termination. Looking back over the notes of the case there is room for suspicion that it may have been one of unrecognized boric acid poisoning.

Neumann states that from 1 part of boric acid in 1000 to 1 in 500 is sufficient to preserve milk. These amounts are not infrequently exceeded. It may be noted that even 1 in 500 corresponds to 17.5 grains per pint and constitutes a very large dose for an infant on milk diet, and is likely in some cases to produce disturbance of the alimentary canal. In ordering milk diet for cases of kidney disease it ought also to be ascertained that the milk supplied is free from excess of boric acid or borax. The use of boric acid or the borates in surgery and their internal administration, though usually free from danger, ought to be carefully guarded in patients whose kidneys are diseased, and immediately discontinued should dermatitis or other toxic symptoms appear. In suspected cases the examination of the urine for boric acid and borax may afford valuable evidence of the absorption of the drug.

---

THE PROGRESS OF OTOLOGY.

The Laryngoscope for January, 1899, contains an article by Lederman with this title. He begins by pointing out that the retrospect of aural therapeutics recalls visions of the "old-time politice" and delayed action. Antiseptic surgery has accomplished much for the energetic aurist and has proven a boon for his suffering patient. The study of otology has made rapid strides during the past few years. Its foundation has been laid by the persistent efforts of clinical research.

To-day we recognize the importance of early and liberal incisions through the drum membrane, in assisting Nature to accomplish her purpose. Under proper antiseptic precautions such assistance frequently prevents suppuration in catarrhal disease of the middle ear. The dry method in the after-treatment of such cases is advocated by a number of observers. Too much moisture weakens tissue resistance. A strip of antiseptic gauze introduced in the canal acts as a serviceable drain. When the oral discharge is copious, it is necessary to resort to gentle douching with warmed antiseptic solutions.

In chronic catarrhal diseases of the middle ear free aeration of this region, together with proper ventilation of the Eustachian tube, must exist before definite results can be obtained. The influence of nasal and pharyngeal disease upon ear affections is now thoroughly appreciated by workers in this field of medicine. Adenoid vegetations in the pharyngeal vault are known to be the direct excitant cause in suppurrative conditions, especially in early life.

Free nasal respiration augments the Eustachian tube's function, and any obstruction to the circulation of air in these channels must necessarily act as an incentive to aural disturbance.

Politzer's air douche and the Eustachian catheter maintain their usefulness in the treatment of middle-ear affections. Delstanche's masseur combined with the Siegel otoscope form a valuable combination for the relief of ankylosis of the ossicular chain. When employed in this manner ocular observations can readily be made, thus avoiding traumatism of the parts.

For some years Dr. Lederman says he has found undoubted improvement in some forms of chronic catarrhal otitis from the use of medicated oils, sprayed through the Eustachian catheter, and then forced into the middle chamber by compressed air. In these solutions benzoinol was used as the "base" on account of its bland quality. The "return catheter" did not prove as serviceable as the ordinary hard-rubber instrument.

Knapp has called attention to the importance of the functional examination of the ear. In ascertaining the acuteness of hearing, he has found the human voice the best test. The tuning-fork is of great value in determining the range of audition. Belzold's continuous tone series is a valuable apparatus of this kind. This "series" extends from the lowest C:ii (15 v. d.) to C' (1024 v.), and consists of ten clamped forks. It is not a
handy affair, and cannot be employed in routine examinations, as too much time is consumed.

As yet no therapeutic discovery has been offered as a panacea for persistent tinnitus. This distressing symptom frequently baffles our earnest efforts. When the tinnitus is due to circulatory disturbances, some benefit may be obtained from the internal administration of cardiac sedatives. Thyroid extract has been recommended by some, and found wanting by others. Thiosinamine (Merck's) has been suggested in cases of tinnitus, where inflammatory products restrict the movement of the ossicles. Keloid tissue has disappeared under the internal administration of this drug, and the supposition is that fibrous changes in the middle ear will also be absorbed. Clinical data upon this subject are as yet quite meager.

The suprarenal capsule has shown marked contractile properties upon erectile tissue, especially in nasal congestions when applied locally or when taken internally. If ringing in the ears is due to an engorged state of the vascular apparatus, this remedy will no doubt prove of benefit. Various surgical methods are offered in the hope of arresting this harassing symptom. Incision along the posterior border of the malleus, with the introduction of a blunt hook through the opening, and repeated traction upon the malleus handle, has been attempted by some with success. Mobilization of the stapes, together with the removal of the incus and malleus, is recommended by other aurists. It is impossible to promise a cure by such treatment, for recorded cases prove that the tinnitus not only returned, but actually became worse after such interference.

Among the remedies regularly employed to overcome suppurrative conditions, boracic acid still holds a prominent place. Antinosine, the sodium salt of nosophen, is recommended as a harmless, non-irritating, and powerful antiseptic. Peroxide of hydrogen has proven itself an excellent pus-destroyer. Formalin in weak solutions is also efficacious.

Trichloracetic acid has been used with good results in stimulating the edges of old perforations of the membrana tympani.

In mastoid involvement early operation is now universally indorsed. When palliative measures have not given the desired result within forty-eight hours, surgical principles should be put into effect. If suspicious of mastoid disease, there is no reason for postponing the radical operation. Delayed ac-
In one hundred and fifty cases of mastoid operations analyzed by Milligan, ten (6\% per cent) were acute involvements and were accompanied by the usual symptoms. In these cases rapid healing followed the opening of the mastoid antrum, with recovery of hearing power. Out of the 150 cases operated upon, ten (6\% per cent) were subacute instances, without much local pain, with a copious discharge and progressive loss of hearing. The other case did not remain under observation. One hundred and two cases (68 per cent) were distinctly chronic in character. Stacke's modified operation was performed in the last series seventy-eight times. Out of this number, sixty-five resulted in complete recovery. All suppuration ceased, and the antratomypanic cavity became satisfactorily covered with skin. The hearing power was not improved by the operation.

This statistical report practically illustrates the position of radical treatment of chronic suppurative otitis. Clinical experience is the criterion upon which rational principles are founded. Conservatism is certainly a worthy quality, but when continuous treatment through the canal fails to accomplish a cure, we must unhesitatingly resort to more heroic methods.

Sinus thrombosis has received much attention during the past few years. Operations upon this channel are becoming more numerous and more successful. Timidity is gradually becoming a thing of the past, and free dissection of diseased areas is now boldly made. Whiting's practical observations upon this affection are valuable contributions. The aurist has to deal with the infectious thrombus, which is due to the presence of chronic suppurative ear disease. Many interesting remarks are made upon the pathology of the disease.

The diagnosis of an existing thrombus of the sigmoid sinus is not easily made. Pain, usually radiating from the ear and extending over the side of the head, with edema of the mastoid and occipital region, are significant local indications. Chills, high temperature, and malaise are systemic symptoms most commonly observed. Pulsation of the sinus has no diagnostic value.

In operating upon sinus cases it is considered best to uncover the sinus at the knee and descending portion. This may be done with the chisel and rongeur forceps. The mastoid antrum should always be opened, as infection spreads from this cavity. The hypodermic needle is of service in locating the thrombus.

Ligation of the jugular vein in these cases is an important element. Where the obstruction does not extend below the jugular bulb, we may not be called upon to tie the vessel. If, however, we are not successful in reestablishing the circulation from below the bulb, Whiting states that it is the operator's imperative duty to ligate the vein immediately. Where toxic symptoms are pronounced, or where metastases are already present, authorities agree that it is necessary to tie the vein as a preliminary step in opening the sinus. When the jugular has been ligated in two places the intervening portion should be resected, as the neck wound heals more rapidly and satisfactorily, and the liability of suppuration is much less. Statistics show that in sinus operations, where simultaneous ligation of the jugular has been performed, the percentage of recoveries is greater.

Labyrinthine deafness is still refractory to our present treatment. In some of these dubious cases pilocarpine and strychnine, together with applications of electricity, have given some improvement. Traumatic involvement of the inner ear is not as serious as a systemic invasion. Hypodermic medication is recommended in specific diseases of the internal ear.

THE PROGRESS OF RHINOLARYNGOLOGY.

The Laryngoscope for January, 1899, has in it an article by Scheffereall, in which he makes an annual review of his subject. He tells us that a new remedy for acute coryza has been suggested by D'Aquitotl, who recommends the application of leeches to the lower portion of the nasal septum. The possibility of sepsis in this application should, however, not be overlooked, this complication being demonstrated by the report of Lenzman, in which general sepsis followed a furuncle at the entrance of the nostril in a strong woman of thirty-six years, which proved fatal in five days. Staphylococci were found in the exudated fluid, but there was no pus.

The advocates for the operation of turbinectomy appear to have suffered a reaction during the past year, and comparatively little has been published on this subject. The operation deserves a well-earned rest. Greville Macdonald has published some further investigations on the importance of the turbinated bodies in the respiratory tract, and
calls attention to the embarrassment of this process after turbinectomy.

In addition to the usual number of reports of foreign bodies in the nasal cavities, several additional cases of the Texas screw-worm have been published, one case described by C. M. Robertson being followed by a fatal result. Cases of occlusion of the choanae are reported by J. P. Clark and Gradenigo, the former describing a complete congenital occlusion, and the latter an occlusion of the right choana.

There has been considerable literature on the subject of the correction of deformed nasal septa, without, however, adding much to our former stock of information. The advantages of a submucous operation have again been brought forward by De Blois, who claims that it obviates the danger of making a perforation, heals more quickly than the ordinary operation, and is not followed by cicatrical tissue, which forms a lodging place for crusts of dry mucus. Quite a simple method for resecting the nasal septum without perforation is recommended by Escat. It consists of injecting four minims of boiling water by means of a hypodermic syringe into the mucous membrane of the concave side, thus stripping this from the cartilage. The convex side is then resected with a bistoury in a vertical direction. After cicatrization the closure is insured by the approximation of the, uninjured mucous membrane to the cicatricial membrane.

Gelatin, which has recently come into favor as a hemostatic in general medicine and surgery, has been recommended in epistaxis by Carnot, who advises it especially in bleeders; he also advocates its use after tonsillotomy. It is applied by means of a syringe or a piece of wool saturated with a five-to ten-per-cent gelatin solution in sterilized water. The addition of an antiseptic has been found not to interfere with the coagulative property of the solution.

Formaldehyde has been added to the list of therapeutic agents in ozena by G. L. Richards, who uses five to ten drops of a forty-per-cent solution in eight ounces of hot water. The electrolytic treatment of this disease continues to be recommended by Rethi and Scheppgrell. The subject of the treatment of ozena by antiphteretic serum has been again brought to the attention of the profession by Holger Mygind, who claims that the injection of antiphteretic serum in genuine cases of ozena is the most effective of all treatments hitherto known. He afterward, however, makes a somewhat contradictory statement when he says that the presence of toxins is of no importance, but that it is the serum alone which acts, as he has obtained equally good results from the injection of patients with the normal serum of horses.

The observation of Gouguenheim's cases at the Lariboisiere Hospital indicated that some good results may be obtained from the use of the serum-therapy in ozena, and shows that any drawback of a serious character may be avoided by using small doses. The author admits, however, that while this is the most convenient method for combating the fetor, hopes of a definite cure should not be held out to the patient.

Regarding the etiology of inflammation of the accessory sinuses of the nose, Howard and Ingersoll have made a careful bacteriologic study, and have demonstrated that with a few exceptions (aspergillus and vermes), inflammation of these cavities is caused by microorganisms, the diplococcus lanceolatus, the pyogenic staphylococci and streptococci, the bacilli of the group of Friedlander's bacillus, the bacillus diphtherie, and the bacillus influenzae being the most important. The bacillus of tuberculosis has also been observed, which shows the importance of making a bacteriologic examination. It is, however, not necessarily pathognomonic of a serious condition, as indicated by a case reported by Gaudier which was successfully treated by opening through the canine fossa, curetting and packing with iodoform gauze.

The influence of plugging the nasal fossae in the etiology of inflammation of the maxillary antrum is shown by St. Hilaire, who reports two cases following this procedure. An interesting case is reported by Molinié, in which the secretion was of a distinct bluish color and was supposed to be due to the development of a pyogenic colony in the frontal sinus of the right side.

In the treatment of empyema of the maxillary antrum the operation of Luc has gained favor during the past year. Luc admits that he is not entitled to priority in this operation, as Scanes Spencer has already described such a procedure, in which the canine opening, however, is not closed at the end of the operation. Caldwell has described the same operation, but without giving details or cases.

In certain forms of headache, especially frontal, E. L. Vansant has found the forcible syringing of the accessory nasal sinuses with a stream of hot dry air a useful remedy. In
some instances the air is medicated, or nitrous oxide is employed.

In the treatment of empyema of the frontal sinus Bryan has somewhat modified the rules described in his original operation. In cases of extensive caries he admits the impossibility of procuring healing in less than from four to six weeks, and therefore advises drainage, for some time at least, through the external opening, instead of at once closing the external wound, as in his original operation. The Ogston-Luc method seems still to hold favor in empyema of the frontal sinus. The Cusber-Czerny operation has been somewhat modified by Barth, who splits the nasal bone and the nasal process of the frontal bone, and forms a wider communication between the nose and the frontal sinus by removing the ethmoidal cells. The wound is sutured after the thorough removal of the frontal sinus membrane, and gives a fairly good cosmetic result.

ALCOHOL AS AN ANTIDOTE FOR EXTERNAL CARBONIC ACID POISONING.

In the New York Medical Journal of January 14, 1899, Dr. A. M. Phelps tells us that Dr. Seneca D. Powell, of New York, has for a long time used in his clinics at the Post-Graduate Hospital an antidote that all have come to recognize as a specific. He alludes to alcohol, and it is not an unusual occurrence to see Dr. Powell, in the presence of the class, catch in his open hands a quantity of pure carboic acid poured into them by a nurse from a bottle. In a few moments the Doctor puts his hands into a basin of pure alcohol, and no escharotic effect is observed whatever from the action of the carboic acid upon the skin. Dr. Phelps says he was somewhat surprised when he first saw this experiment, but when he recognized the result he was convinced of the scientific fact. At the present time he is flushing out abscess cavities with pure carboic acid and washing them out a few moments later with pure alcohol. In empyema Dr. Powell, after making a large opening in the chest wall, washes out the cavity with a ten-per-cent solution of carboic acid, after which pure alcohol is used, and no bad effect has thus far been observed from this treatment. The cavity of the pleura is rendered aseptic. From personal observations and demonstrations in the use of pure carboic acid followed by the use of alcohol, Dr. Phelps says he can state to the profession positively that we have in alcohol an absolutely safe and sure specific against the escharotic action of pure carboic acid. And he believes that this fact should be given wide publication to the profession and even to the laity, because in cases of carboic acid poisoning with homicidal intent, if immediately after the administration of the poison alcohol was thrown into the stomach of the individual, the poisonous effect of carboic acid would be at once neutralized.

THE CLINICAL EFFECT OF THYROID EXTRACT UPON FIBROID TUMORS OF THE UTERUS.

The Medical News of January 14, 1899, contains an article by Polk upon this theme. In its course he tells us that the net result in each case in which he has tried this treatment has been improvement, the greatest existing in those who took the treatment longest. Its manifestations were: (a) control of the menstrual flow; (b) arrest of the growth and, in some cases, diminution of the size of the tumor and apparently softening of it; (c) disappearance of pain and diminution of tenderness in the growth, and also of the sense of abdominal and pelvic distention, increase of muscular and nervous energy; (d) betterment of general nutrition, manifested at first by slight loss and then by return of flesh; an improved state of the skin, hair, and nails, and the substitution of good color for the appearance of anemia. As might be inferred, the condition of the bowels was likewise improved, although, as we shall see later, this was counterbalanced in some cases by gastric disturbances. It must not be supposed, however, that this was the sole drawback. There were others, but none was insurmountable—all belonged to the state now designated “thyroidism,” but were manifested in its milder form because of the close watch kept upon the remedy. In every instance tachycardia was the most common drawback; next, restlessness and sleeplessness, when the drug was taken at bedtime; and lastly, indigestion.

It is evident, then, that the remedy is efficacious, but when conceded a place it must be compared with those accepted and now in use. To this end Polk, therefore, submits the following observations: Ergot, with or without digitalis, has failed to arrest menorrhagia in about fifty per cent of his cases, and when successful it has been continued, as a rule, in the face of an impairment of digestion and bowel action, interference with the heart’s action, and sometimes its use has been ac-
companied by a good deal of mental depression. Even though retarding growth for a time, it loses this action after a while. It aids in the expulsion of submucous fibroids and in the conversion of interstitial into subperitoneal and submucous growths. The general health is apt to deteriorate much in the prolonged use of this drug. The suspension of the ergot has been followed usually by relapse into a state about as unfavorable as when it was commenced. Electricity has given little satisfaction, except when used as a cautery to the mucous membrane of the uterus, and this action has appeared to be in no way superior to the use of the curette, and is more dangerous. Curettage involves anesthesia and invasion of the uterine cavity—not once, but repeatedly in all cases. Ligation of the uterine arteries is an operation sub judice, his experience being against rather than in its favor. Removal of the ovaries is an operation which offers, perhaps, a better result than mere ligation of the uterine arteries, but it is an open question with many having a patient fitted for a laparotomy if total extirpation is not better. Myomectomy, either submucous or subperitoneal, and total extirpation are procedures which stand by themselves, facing no rivals in their appropriate fields, so no comparison with any medicinal or hygienic treatment can be instituted with them.

This, therefore, reduces the competitors of the thyroid treatment to the purely medicinal—such as ergot and digitals—to electricity, and what may be called the palliative operations, such as curettage, ligation of the uterine arteries, and oophorectomy. Polk recognizes that it is premature to institute a comparison between this thyroid treatment and the so-called palliatives, yet he has ventured upon it for the sole reason that his individual experience has seemed to justify it. If, therefore, the thyroid treatment can be shown to possess the power to keep down the menorrhagia, metrorrhagia, and hystorrhea of fibroids, if it can control their growth and annul the pain inherent to many of them, it is superior to any medicinal treatment now in vogue; is better than electricity, curettage, or ligation of the uterine arteries; is preferable to oophorectomy, and in all smaller tumors it should be carefully employed before myomectomy or total ablation is resorted to, excepting, of course, cases in which the growth is merely submucous or in which malignant or septic changes are suspected. All such cases, in common with the larger growths, come within the pale of myomectomy or total ablation, and, as already admitted, are outside the field of this comparison.

As to the possibility of an efficient combination of some one or more of these credited agents or procedures with the thyroid treatment, Dr. Polk says it has appeared to him as probable that some cases might be best reached through some such combination—for instance, cases of excessive menorrhagia might do best with a preliminary destruction of the diseased mucous membrane with the curette, to be followed soon after by the thyroid treatment. Then, again, in combination with ergot, the two to be given simultaneously or successively as the symptoms suggest or warrant. The preliminary use of the curette appeals to one in the class of cases mentioned, but cannot be suggested as a routine measure for the reason that he has found it unnecessary in two of his cases. The combination treatment with ergot has seemed beneficial when it is well borne, three patients having been so treated. After the suspension of the thyroid, these patients were placed on ergot, and it appeared to him that the good effects of the thyroid were maintained the better. He had previously observed these patients about six months upon the thyroid alone, and subsequently made observations for the same period of this combined treatment. In two others similar observations were instituted with the combination of thyroid and electricity, but he cannot say that he is convinced of its efficiency. Polk wishes it to be understood that in using electricity he does not carry the pole beyond the cervical canal, his experience with its intra-uterine application, except under anesthesia, having shown that an intra-uterine septic inflammation was apt to be set up, an accident only too sure to occur in the absence of the kind of antiseptic technique which is necessary and possible only under anesthesia.

Dr. Polk concludes his paper by saying that as yet he has not been able to determine which of the two classes of fibroids is most amenable to the thyroid treatment, but he inclines to the belief that the nearer the growth approaches the type of the pure myoma, as distinct from the fibromyoma, the better the ultimate result with the treatment. The bleeding, however, is more quickly controlled in the fibromyomata. This much one would infer from the comparative bloodlessness of this type; and yet, while leaning toward favorable conclusions, we must not
REPORTS ON THERAPEUTIC PROGRESS.

forget that the effect of the long-continued use of this remedy in these cases is undetermined. We know of the more acute effects, viz., the headaches, tremors, gouty and rheumatic pains, general debility, persistent vomiting, and profuse diarrhea; the tachycardia with its dyspnea, perhaps even fatal, we know of, but we do not know how easily these symptoms are controlled by regulating the dosage or stopping the remedy. But have we information of some possible general degenerative change in consequence of prolonged use? For answer we are forced to consult myxedemas, for they are the only cases which, so far, have been long exposed to the drug. It is true that here we have a disease clearly due to a thyrosis, and in giving the drug we merely return that which Nature requires, so it is fair to assume that nothing but good can come to myxedema from proper dosage with the thyroid. But so far as fibroids are concerned we must remain in uncertainty upon this point until the condition of the thyroid gland and secretion can be determined. Until such information is forthcoming we must get our encouragement from analogy. Both diseases are common to women and common at about the same period, both are characterized largely by an increase of the connective tissue elements, and both are prone to uterine bleedings. This similarity is too general to be more than suggestive, particularly when it is offset by the dominating influence of the ovary whose removal generally determines the subsidence of fibrotubercle disease. But in the absence of any contraindication the analogy may be taken as a justification for the prolonged use of thyroid extract in this disease, with the proviso that we be alert, be keenly inquisitive as to the state of the circulatory, renal, nervous, and digestive systems, stopping or curtailing treatment as warnings arise.

It may not be out of place to suggest a minimum meat diet for these patients, and to advise rest—rest even in bed when the tachycardia is too persistent and troublesome—or a change of preparation, as some have more of this poisonous action than others, probably due to impurities, such as ptomaines, leucamines, or the substitution now and then of iodothyrine, using the two alternately.

He points out that the objects sought by the physician are to maintain life, to support the heart, to control fever, allay suffering, and lastly treat complications.

The maintaining of life includes the nursing and diet, which are too familiar to require any details. Dr. Manges says, however, he wishes to emphasize the importance of watching the stomach, for not enough attention is paid to ascertain whether it be unduly distended with gas or improperly digested food; even liquids may be improperly disposed of by the stomach. Routine percussion of the stomach is far more important than routine examination of the lungs. The heart must be spared in every way; let its burdens not be unnecessarily increased by upward displacement from the unduly distended stomach and intestines. All articles of diet which may produce flatulence must be rigidly excluded, and the milk must be adapted to the patient both in quantity and in preparation. Do not overfeed these patients; the disease is a very short one, and the patient's surplus fat and tissues will supply any deficit in the diet. Spare the stomach from undue medication as much as possible, and use the hypodermic method in preference. Give water freely, either cold, hot, or carbonated (unless the patient is cyanotic), for it allays the thirst, reduces the fever, and increases the elimination of toxins by promoting free diuresis. For the latter purpose the combination of a light Moselle wine with an alkaline mineral water is exceedingly useful.

As well described by Douglas Powell, the heart dangers are three in number: (a) Impaired nerve power on the part of the pneumogastric branches of the cardiac plexus; (b) impaired nutrition of the hard-working heart muscle from insufficient or badly aerated blood-supply; (c) mechanical tendency to overdistention of the right cavities and to depletion of the left cavities of blood.

The drugs which best meet these indications are strychnine, caffeine, and nitroglycerin. Strychnine and nitroglycerin are best given in reliable tablets, the caffeine in solutions of the benzoate or salicylate. If the results are not promptly obtained the drugs should all be administered hypodermically. Nor should we hesitate to use them freely, for the action of each is clean-cut, and any overdosage can be recognized very readily. His own experience has convinced him of the value of large doses of strychnine, to which Roosevelt called attention, in tiding a
heart through the crisis. For the same purpose we may also resort to the hypodermic injection of camphor in sweet almond oil. Osler also reports good results from hypodermoclysis. A struggling heart is often aided by an ice-bag over the precordium.

Van Santvoord has very recently published an interesting paper which throws an entirely different light on the subject of heart failure in pneumonia. His views are based upon the important experiments of Romberg, which proved that the cardiac weakness in pneumococcus toxemia is due mainly to a vasomotor paralysis, it being clearly demonstrated that arterial pressure is low as the result of relaxation of the peripheral blood-vessels. This is entirely opposed to the prevailing view that the characteristic pulse in pneumonia is one of high tension. If subsequent observations prove the correctness of these views, we should be cautious in the use of nitroglycerin for obvious reasons, and should restrict its use to the temporary relief of embarrassment of the right heart.

These experiments may also clear up the question of the use of digitalis in pneumonia, about which so much bitter discussion has been waged. The extreme views of Petresco have not found favor. In answer to the low mortality of 2.06 per cent reported by him and his school in 825 cases (Dr. Manges believes most of these cases were in soldiers, his statistics being those of the military hospital at Bucharest), he says he may cite the extremely low mortality of 3.6 per cent in 40,000 German soldiers. Petresco has certainly demonstrated that the danger from these colossal doses of digitalis (12 grammes, or 180 grains, daily) is small, but according to Reiner they must not be continued more than two days at the utmost. Another explanation of the tolerance for these large doses may be found in the experiments of Brunton and Cash, which clearly show that the action of digitalis is lessened in febrile conditions. A safe guide for the use of this drug is that given by von Juergensen: "Digitalis is indicated as soon as the pulse rises in frequency, and at the same time becomes irregular without any demonstrable cause, in patients whose hearts were weak before the attack, or in patients whose hearts have weakened during the course of the disease. The fulness or emptiness of the pulse is important in determining this; if it is still full we can afford to wait a little, especially toward the end of the disease, when not infrequently one of the indications of an impending favorable turn is slight irregularity of the pulse."

In considering the control of the fever it should always be borne in mind that temperatures ranging up to 104° F. are as normal a feature of pneumonia as dyspnea and rusty sputum. The view which is now generally accepted is that fevers up to this point are the normal reaction of the organism to the invading pneumococci. That these "normal" fevers are even of service to the patient is well shown in a table published by Douglas Powell, in which he demonstrates that pneumococci grow to perfection at 35° to 37° C. (95° to 98.6° F.), and not at all at 40° to 42° C. (104° to 107.6° F.). He also directs attention to the value of the leucocytosis of fever in removing torpid or inert cocci. But, as in all symptoms of pneumonia, we must individualize, for in some patients a fever of 102° F. may inflict more damage than 105° may in others. The thermometer, then, is not the only gauge as to the question of the fever being unduly high; the true guide is the patient's general condition.

The use of large, flat ice-bags is the most convenient method for the reduction of undue fever, two or three being applied to the affected area. They are usually well borne and add not a little to the patient's comfort. The ice-bag, however, is no specific against pneumonia, as Mays would have us believe. Occasionally the prolonged use of ice-bags causes intercostal neuritis, as the author has observed in two cases. When the nervous symptoms are very pronounced we should not hesitate to resort to cold baths, using them in the same way and on the same general principles as in typhoid fever. If less heroic measures be preferred, prolonged immersion in lukewarm baths (90° F.) may be used instead. The contraindications to cold baths are very extensive consolidation of the lungs, marked adynamia, very rapid breathing, feeble heart action, and arteriosclerosis. Cold sponging and cold packs are often useful. Baruch recommends moist compresses which envelop the entire chest; their antipyretic effect is not very marked, and extensive furunculosis (due to the staphylococcus aureus) was noted in two cases at the Mount Sinai Hospital. The large doses of quinine which formerly found so much favor are now seldom employed. The routine use of the coal-tar products is now, fortunately, discarded; the occasional use of them in small doses is not objectionable.

The most striking indication under the
head of relieving suffering is the relief of the pleuritic stitches and the distressing coughs, which wear out the patients and rob them of their much-needed sleep. These are best relieved by the hypodermic injection of morphine, which may be resorted to as soon as possible without unnecessarily weakening the patient by temporizing with other means. The Paquelin cauter is often acts magically in quieting pleuritic irritation; no one who has ever used it will temporize with sinapisms, blisters, leeches, poultices, etc. The ice-bag is also very valuable, but does not act as promptly as either of the above. Quite recently Manges has been using a new drug, heroin (diametic-acid-ester of morphine), as a sedative for these thoracic symptoms, and so far as his present experience will allow him to judge, he believes that this drug will be found to be a valuable aid in quieting distressing coughs. It has acted well in some cases which were not relieved by codeine. It is given in tablet triturates or powders, in doses of one-twelfth to one-sixth of a grain every four hours.

Sleep is an imperative necessity for the overworked patient with pneumonia; to secure it is one of the most imperative indications in the treatment. The nervous exhaustion of which it is often the first herald may be prevented by the timely use of hypnotics. Of these morphine and chloral are the best. Chloral, when combined with a cardiac tonic, is perfectly safe. Balfour, the veteran clinician of Edinburgh, is most enthusiastic in his praise of it. We may also resort to cold packs or alcohol.

Of the value of oxygen in the relief of dyspnea and cyanosis it is difficult to give a final judgment. The opinion is slowly but surely gaining ground among the great clinicians that oxygen has been much overrated in the treatment of pneumonia. Theoretically its employment seems to be so well founded and its application is so simple, the apparent relief so striking, that the universality of its use is not at all strange. But does it really do any good in those cases in which we want its effects most? The primary effects soon wear off in serious cases, and the dyspnea and cyanosis increase in spite of its free use. Let the enthusiast for oxygen remember that the lung is just as consolidated immediately after the crisis as it was before it, and yet what a change there is in the patient's breathing. This proves that the dyspnea is not entirely mechanical in origin as is generally thought, but is mainly the result of the pneumococcus toxemia. In tiding the patient over sudden attacks of dyspnea and cyanosis oxygen is most useful.

Of the complications the most important are pleurisy with effusion, empyema, pericarditis, and endocarditis. The treatment of these conditions in pneumonia differs in no wise from that ordinarily pursued, and hence requires no special discussion. However, it may be added that effusions into the chest, either serous or purulent, ought to be removed as soon as the amount of fluid becomes large enough to interfere with the lung in any way.

**BICHROMATE OF POTASSIUM IN THE TREATMENT OF CHRONIC GASTRIC ULCER.**

Dr. T. McHardy, in the Scottish Medical and Surgical Journal for December, 1898, refers to the researches of Professor Fraser, of Edinburgh, on the value of bichromate of potassium in chronic gastric disease, and records the case of a woman under his care who had suffered from chronic gastric ulcer for twenty years. She had been bedridden for a year; the stomach was very irritable, rebelling on the most trifling indiscretion in diet. Epigastric pain was so severe as to demand constant recourse to morphine. Vomiting and hematemesis accompanied all ingestion of food, and nutrition had to be accomplished _per anum._ Anemia and emaciation were marked; there was anxiety, with quick, weak, and irregular pulse, and dry coated tongue. Flatulence and constipation, with dry, hard stools of a very dark color, often containing bloody mucus, were present. The abdomen was tense and distended, the stomach dilated and very tender on pressure, and a distinct peristaltic action could be felt extending from the fundus to the pylorus.

Pain was referred to two circumscribed spots, each about the size of a dime, lying over the smaller curvature, and often shooting through to the back, especially to the left of the last dorsal vertebra. Occasionally pain became more widely distributed, and when flatulence was severe it extended into the scapular and clavicular regions. As food had been withheld for some days, the vomited matter contained only blood and mucus, which threw out a sour, disagreeable odor, and gave a strongly acid reaction.

To get rid of the mucus, and render the stomach as empty as possible, McHardy first washed it out with a weak solution of boric acid. This had the direct effect of increas-
ing the hemorrhage, and after a subcutaneous injection of ergotin, and the application of an ice-bag to the epigastrium, this symptom quickly subsided. On May 14, 1897, he first administered a sixteenth of a grain of bichromate of potassium, dissolved in an ounce of distilled water. This was immediately followed by such violent pain and sickness that he was compelled to give an injection of morphine. After six hours the bichromate was resumed, and on this occasion he observed a decided improvement in the consequent pain and sickness, and although these unpleasant consequences continued to follow each successive dose for a time, still he noted a gradual abatement in their duration and intensity up to the fifth day, when the pain completely ceased. The sickness, however, persisted during the following week, but in a greatly modified degree. On the 18th of May the dose was increased to a twelfth of a grain, and administered every sixth hour as formerly. This was continued up to June 8, by which date the entire group of gastric symptoms had entirely subsided.

As it was now evident that the anemia had in no way benefited by the treatment, carbonate of iron and a solution of red marrow were substituted for the potassium salt. Under this the anemia rapidly disappeared, and after being continued for a month the only remaining symptom was constipation. As the stomach at first rejected every form of nourishment given, feeding by nutrient enemata was maintained for a week. She was then allowed a tablespoonful of milk and lime-water, repeated every half-hour. After some days milk-arrowroot, yolk of egg, and bread pap were cautiously added to the dietary, and at the end of six weeks she was permitted to share the common food of the family. On visiting her on the 12th of February last the author found her in excellent health and spirits. Her gastric troubles, with the exception of a mild form of indigestion, had never recurred. Her bodily weight had increased three stone, and she could discharge with comfort her usual household duties.

The author calls attention to the fact that vomiting, which previously had been a most distressing symptom, ceased after the first dose of bichromate. This result he has experienced in other cases, and in a recent case of chronic gastritis with persistent vomiting, which had defied several different forms of treatment, its administration was attended by the happiest results.—*New York Medical Journal*, Jan. 7, 1899.

**REPORT OF EIGHT CASES OF PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN, WITH INJURY TO THE HOLLOW VISCERA.**

**Winslow (Annals of Surgery, October, 1898)** reports a number of interesting cases. In the first a patient aged sixty years was shot with a pistol. The ball entered the abdominal wall about four inches to the inner side of the right anterior superior spine of the ilium, and about the same distance above Poupart's ligament, passing through the ileum; it could be felt under the integument of the right buttock. He was seen eighteen hours after he was shot. Some fecal and foreign bodies and adherent blood-clots were found in the peritoneal cavity. The small intestine was penetrated in four places, in the neighborhood of the ileocecal valve, three of the wounds being close together, whilst the fourth and largest was an inch in length and situated about ten or twelve inches from the others. Two of the wounds were separated from each other by only a narrow bridge of intestinal wall. Three were small, and required from four to six Lembert sutures for their closure, whilst the fourth, which was large, nearly horizontal in direction, and with widely everted edges, was sutured with ten or twelve Lembert sutures, the line of suturing being transverse to the long axis of the bowel, in order to avoid an undue narrowing of the gut at that point. As there was some bleeding from behind the peritoneum, the parietal incision was not sutured, but was packed with gauze. The patient was somewhat shocked by the operation, but rallied promptly. He was sustained with nutritive enemata for several days, and at the expiration of five days began to take small quantities of milk by the mouth. The gauze packing was removed on the sixth day and the incision was closed with buried sutures; union promptly occurred. A week later there was an elevation of temperature, and an induration was found in the right iliac fossa. The induration was incised, some pus escaped, and a free hemorrhage occurred. As the vessel could not be ligated, the wound was packed. Five days later a pulsating lump was discovered in the right iliac fossa. The patient was again anesthetized, a free incision made along and above Poupart's ligament, the deep circumflex artery was exposed and ligated, and a mass of decomposing clots was removed from behind the peritoneum. From this time the patient made an uneventful recovery. In this case
a median laparotomy was not done, as it was known that the bullet only traversed the right side of the abdomen, and could be felt under the integument of the right buttock, from which position it was incised some days later. The ball had cut the deep circumflex iliac artery and then passed through the ilium. The patient is still living in good health.

The second case was fifty-eight years old. He was struck by a buckshot in the left side, just below the apex of the heart. Examination with a probe showed that the wound led into the peritoneal cavity, and shortly afterwards blood was vomited in clots, showing an injury to the stomach. A perforation was found in the anterior wall of the stomach, from which gas escaped, but no extravasation of the contents had occurred. The opening was closed with Lembert sutures, and, after removing the discolored edges of the bullet track with scissors, the external incision was sutured. No other perforation of the stomach could be found, and it is uncertain what became of the bullet, as it was never found in the feces. He was kept in bed, absolutely quiet, and no food given for several days. A severe bronchitis set in on the fourth day, but this was of short duration. The external wound suppurred, but as the peritoneum had been sutured separately, the abdominal cavity was not invaded. The patient recovered.

The third case, aged twenty-five years, was shot in the left side of the abdomen, about four inches above Poupart's ligament, and two inches from the median line. Two hours after the infliction of the wound a median laparotomy was performed, the incision extending from the umbilicus to the pubes. At this time the patient was in good condition, no shock having occurred. Five perforations of the ileum were found and three of the mesentery. There had been but little hemorrhage, and no escape of intestinal contents. The five intestinal perforations were closed, and what was supposed to be a careful search of the intestines for other perforations was made. The abdominal cavity was flushed with warm sterilized water, and the external incision closed without drainage. The patient collapsed under the operation, and it became necessary to complete the toilet with less care than would otherwise have been taken. Death took place on the fourth day after operation. An autopsy revealed a general peritonitis and an undiscovered perforation in the angle of junction of the ileum with the cæcum. The bullet was found in the cæcum. The other intestinal wounds had healed firmly.

The fourth case, aged sixty-six, was shot about 8 A.M., and was admitted to the hospital within an hour. He had received a bullet in his abdomen on the right side, and median laparotomy was done as soon as he could be prepared for operation, about two hours after he was shot. Seven holes in the small intestine were sutured, and a search not revealing any further wounds, the abdomen was closed. He was not at all shocked by the operation, and seemed to be in a favorable condition. Vomiting of blood soon set in, and he died with symptoms of peritonitis in twenty-four hours. The coroner's inquest revealed an additional wound in the sigmoid flexure; the No. 38 ball lodged in the left side of the sacrum. The bullet had traversed the abdomen from the right side to the left.

The fifth case, aged twelve years, was shot with a 22 pistol at 5 P.M., and was admitted to the hospital about five hours later. The bullet entered the abdomen slightly to the right of the middle line and about midway between the ensiform cartilage and the umbilicus. Laparotomy was done about 11:30 P.M., the incision, four inches in length, passing through the bullet wound and extending to the level of the navel. Upon opening the abdomen a considerable quantity of bloody clots was found, and upon removing these it was seen that the missile had passed through the thin edge of the right lobe of the liver, making a track about one inch in depth through this organ; it then traversed the transverse mesocolon, and wounded the jejunum in five places. The intestinal wounds were ragged, with everted edges, and liquid feces escaped from the openings. From four to six Lembert sutures, of silk, were required for the closure of each wound, the suturing being transverse to the long diameter of the intestinal canal, in order to prevent any contraction of its lumen. The intestines were cleansed and gauze was packed around the wounds in the liver, and strips allowed to project from the external wound, which was sutured. He was allowed soft toast, eggs, and mashed potatoes in about three weeks, and returned to a normal diet within a month. This patient had been wounded six hours before the laparotomy was done. The bullet was not found, nor, so far as is known, did it pass per rectum.

The sixth case, aged forty-four years, was
shot about 3 P.M., and admitted to the hospital one hour later. The bullet entered the abdomen about one inch to the right of the middle line, and one inch below the navel. Laparotomy was performed at 5 P.M. The incision passed through the track of the bullet, and revealed six ragged holes in the small intestine, and one through the great omentum. All bleeding vessels were ligated, and the wounds in the intestine were closed with rectangular Lemert sutures (mattress sutures), the line of sutures being placed transversely to the long axis of the intestine, in order to prevent any narrowing of its lumen. This operation, like most of those performed for similar injuries, was done by an artificial light. He was not materially shocked by the injury or operation, and was put to bed in fairly good condition. Strained soup was given at the expiration of a week. In about one month he was permitted to return to an ordinary diet.

The seventh case, aged twenty-three years, was shot at 11 P.M., and was admitted to the hospital ten hours later. The bullet entered the right side of the abdomen, about the tip of the eleventh costal cartilage, and an incision was made in the right linea semilunaris, eventually extending from the costal arch to the pelvis. Operation was done eleven hours from the time of injury. He had vomited the contents of the stomach, but without any admixture of blood. Upon opening the peritoneal cavity it was found filled with dark blood, bile, and intestinal fluids, which had gravitated even into the pelvis. The bullet passed between the liver and stomach, and opened the first portion of the duodenum, making a ragged wound about an inch in length, from which blood, bile, and fluids exuded freely. This opening was closed with considerable difficulty, on account of its inaccessibility, but finally a double row of Lemert sutures was placed, each row consisting of about ten stitches. The peritoneal cavity was flushed with hot sterile water and carefully mopped out, and a large glass drainage tube placed between the stomach and liver, and another in the pelvis, and the parts packed with sterile gauze. The lower part of the wound was sutured, and the upper part left entirely open, with gauze sticking out, as it was not thought that recovery would occur if free drainage was not provided. This patient suffered little or no pain, and for a man desperately wounded made an absolutely uneventful recovery. The bullet, a No. 38, was passed per rectum on the sixteenth day. Why the bullet did not pass entirely through the duodenum is a mystery, but in order to be sure that it had not done so the greater and lesser omenta were torn through and the posterior surface of the stomach and duodenum examined.

The eighth case, aged twenty-seven years, was shot in the left side of the abdomen, the bullet entering about two inches below and to the left of the umbilicus. Laparotomy was done about two hours after injury, the incision being placed in the median line. There was considerable bleeding, which was controlled by ligating the lacerated mesenteric vessels. The injuries sustained were three holes in the mesentery and five perforations of the small intestine. These were accurately closed, and the abdominal cavity cleansed. The patient took the anesthetic very badly, and the operation had to be completed in haste. He reacted, however, but complained of much pain, and vomited frequently. His temperature fell and his pulse increased in frequency, death occurring on the third day. Autopsy showed the stitches intact, some plastic peritonitis, but no purulent infection. No perforations were overlooked, and he appeared to have died of acute sepsis.

**THE OPERATIVE TREATMENT OF HEMORRHAGE FOLLOWING CONTUSION OF THE KIDNEY.**

NASA (Berliner Klinische Wochenschrift, No. 34, 1898) was compelled to extirpate an injured kidney because of the profuse bleeding from it incident to traumatism. He classes the cases of kidney lesions with hemorrhages as follows:

1. Those in which there is a discharge of a large quantity of blood, the forerunner of a fatal collapse.
2. Those in which the bleeding is long continued and persistent, threatening death from anemia.
3. Those in which the primary bleeding shortly stops, but is later followed by a sudden severe hemorrhage, probably due to the bursting of a traumatic aneurism. In this latter class are not to be included those cases in which there is a sudden evacuation of discolored urine which has for a time remained encysted.

Cases belonging to the first and third groups should be subjected to immediate operation, especially when there is reason to believe that hemorrhage is taking place into the peritoneal cavity.
In the second group the surgeon must be guided by indications. At times hemorrhage may be stopped by ligature or packing. When the kidney is greatly damaged, resection or extirpation should be practiced at once. This operation is always indicated when the renal artery is torn. The best incision is the oblique one, running from the eleventh rib downward and forward to Poupart's ligament.

COXA VARA.

Fabrikant (Revue de Chirurgie, Nov. 10, 1898), who has contributed a very complete article upon the subject of incurvation of the neck of the femur—the so-called coxa vara—states that there is little difficulty in diagnosing this condition, since the symptoms are sufficiently characteristic. The symptoms are:

1. Shortening, measured from the anterior superior iliac spine to the external malleolus.

2. Absence of shortening, measured from the tip of the trochanter major to the external malleolus.

3. Upward displacement of the trochanter major together with projection.

4. Slight limitation of abduction and inward rotation.

5. Absence of pain on passive movement.

To these symptoms may be added limping, occasional pains radiating to the knee-joint, and a tendency to become easily fatigued by walking. Distinction may be made between this affection and coxitis, by the absence of inflammatory symptoms. An upward displacement of the trochanter, due to an old fracture of the neck of the femur, might lead to confusion, but in this case there would be a deposit of callus and a history of trauma.

The prognosis of the affection must be guarded as to restoration of the normal condition. During the early stages orthopedic treatment often produces great amelioration or even apparent cure. Absence of treatment at this time may lead to great crippling, as shown by a case described by Schultz. A child three years old attracted surgical attention by a limp, which increased. She had no pain, and seemed well in every other way. She simply experienced a sense of fatigue in the hip-joint, so that walking was tiresome. She was not, however, confined to her bed. Shortening of the leg was discovered by the doctors, but no therapeutic means were taken to prevent its increase. The sole of the shoe on the affected side was simply made thicker.

As a result of this treatment, when the child was eleven years old, the leg was three inches shorter than its fellow; and because of functional disturbance the resection of the articulation became necessary. The orthopedic treatment consisted in massage and extension. Extension should be worn night and day. At night it is secured by plasters and weight; during the day by an extension splint.

When patients present themselves after the deformity is well marked an operation is often required. Hofmeister recommends subtrochanteric osteotomy.

---

ESOPHAGEAL STRicture.

Kelynack and Anderton (Medical Chronicle, November, 1898) observed forty esophageal strictures in 4859 autopsies—that is, a percentage of 0.82 in all cases submitted to general pathological examination. Of these forty cases only six, or fifteen per cent, were of a simple or fibrous nature. The remainder were undoubtedly malignant. Of the thirty-four malignant cases a vast majority were in the male. As in the case of fibrous stricture there was an increasing frequency from above downward, twenty-five cases being observed in the middle and lower thirds of the gullet. Pulmonary congestion and edema occurred in about two-thirds of the total number of cases, and bronchopneumonia was present in nine cases. The average duration of the disease from its earliest symptoms to the final issue of the case, as reckoned from the history of twenty cases, was 7½ months. In only one instance did the course exceed thirteen months, and in only one was the course of less than three months' duration. There was a family history of malignant disease in but three cases, in five cases there was a history of excessive indulgence in alcohol and smoking, in four cases there had been exposure to the hardships of life.

Griffith in the same journal describes a case of fusiform dilatation of the esophagus without organic stricture. He states that dilatation above the stricture of the esophagus is far from common, since food if unsuccessful in passing through the narrowing into the stomach does not accumulate above the obstruction, but is rejected shortly after being taken. He believes that in his case the condition was due to atony, and probably a congenitally narrowed cardiac orifice. The esophagus had evidently acted as a reservoir.
and was thrown into folds; hence an attempt to diagnose the condition by the passing of a sound might readily lead to the faulty diagnosis of stricture. Auscultation of the esophagus might help in forming an opinion as to dilatation; since if a large amount of fluid can be apparently swallowed, and no gurgling, or only very feeble gurgling, can be heard to the left of the ninth or tenth dorsal vertebra behind, a condition of dilatation may be strongly suspected.

The cases recorded have been characterized by great chronicity.

In the treatment of the confirmed condition little can be done beyond advising the patient to eat slowly, to masticate thoroughly, and to take a small amount of food at a time, so as to avoid aggravating the condition by mechanical disturbance. If the oncome of the condition is suspected, as it may be if it follows a severe blow on the chest, temporary rest to the esophagus by rectal feeding, or by the use of the stomach-tube, may be advisable, followed by gentle galvanism and the observance of the above noted precautions in eating. Feeding by the stomach-tube should be employed in all cases where possible, in which the patient is manifestly losing ground, and in some cases gastrostomy might be required.

THE TREATMENT OF FAVUS.

Peterson (Archiv für Dermatol. u. Syph., 43 Bd., 44 H., 1898), after first softening the crust of favus by means of a one-per-cent carbolated vaselin ointment and washing it away by soap and water, paints the diseased area with tincture of iodine. It is not necessary to remove the hair.

THE ORIGIN, EFFECTS, AND TREATMENT OF SEPTIC INFECTION OF THE URINARY TRACT.

In a discussion upon this topic held at the annual meeting of the British Medical Association, Newman (Journal of Cutaneous and Genito-Urinary Diseases, January, 1899) states that simple retention of urine does not give rise to septic inflammation; that small cultures of pyogenic microorganisms when introduced into the healthy bladder fail to produce sepsis; that if the mucous membrane of the bladder be injured prior to the introduction of microorganisms, sepsis immediately occurs; that if artificial retention of urine is induced from six to twenty hours after the introduction of the septic organisms into the bladder, suppurative infection of the mucous membrane follows. Serious injuries and diseases of the general and nervous systems at once decrease the natural resisting power of the bladder. Septic lesions of the kidney are induced by infarctions, arising from infective emboli, conveyed through the blood-streams from remote tissues or organs; invasion along the lymphatics of the urinary system; contagion along the lumina of the excretory ducts; septic contamination; contiguity of abdominal organs; or by wounds. When the infection is by the blood both kidneys are generally affected, and the abscesses are small and multiple, and on account of the arrangement of the blood-vessels are more abundant in the cortex.

By means of lymphatic vessels of the ureter a violent septic poisoning may be induced in the kidney without the mucous membrane of the ureter or pelvis being involved. Thus after an operation upon the urethra or bladder a violent rigor and suppression of urine may be followed by renal hematuria or by collapse, which may terminate fatally.

Rorsing, basing his opinion upon personal examination of about 200 cases, holds that two groups of bacteria will be found which govern the urinary region: (1) those which decompose the urea (staphylococcus pyogenes aureus and albus, proteus Hauser, various diplococci and staff bacteria, both pyogenic and non-pyogenic), and (2) those bacteria known under the name of coli bacilli. The reason for this is that the two main sources of infection are the urethra and the intestines.

Normally the urethra contains microbes which decompose the urea. Their number is greatly increased by inflammation. Coli bacilli swarm in the intestines. Infection is conveyed through the blood much more frequently than is generally supposed, especially from the intestines. Infection from the urethra most frequently takes place by the instruments carrying germs from the urethra into the bladder.

Infection may pass from the urethra to the bladder without instrumentation: (1) when there is a posterior urethritis with collection of pus behind a stricture, or when the mucous membrane is markedly inflamed; (2) in case of incontinence, when the sphincter fails as a carrier, the oozing stream forming a road of communication.

Next in frequency to infection of the urethra comes that from the blood, the intestines being
the most frequent source. Such spontaneous infection often appears in patients with symptoms of acute or chronic enteritis, especially colitis with chronic constipation. This form of invasion takes place most frequently in the kidney, because it is in this organ that the blood most frequently deposits microorganisms. Many of these cases commence with an acute but slight nephritis, and the inflammation in the majority is confined to the pelvis.

As opposed to Guyon, who believes that almost all infectious diseases of the urinary tract are due to the bacterium coli, and that the severest and most dangerous form of cystitis, the fatal ascending nephritis, and the violent cases of urine infection resembling septicemia, are due to that microbe, while the urea-decomposing microbes are of secondary importance, Rosing believes the exact contrary. He particularly notes a difference between bacterium coli and the urea-decomposing microbes in calculous pyelitis. Under the actions of the latter the concretions grow rapidly from phosphatic deposit, while under the influence of the former they may often crumble rapidly—that is, bacteria coli may have a litholytic influence on calculi.

As to the prophylaxis of infection. Vaseline should be abandoned as a lubricant, since it is not washed away by irrigating fluids, and while adhering to the mucous membrane also imprisons the microbes. Rosing advocates sterilized olive oil or glycerin. Steps should be taken to kill microbes which have been introduced, especially in cases of prolonged examination. This is best done after examination by injecting into the bladder through a catheter from four to six ounces of a two-per-cent solution of silver nitrate, which is allowed to remain for three or four minutes, after which the bladder is washed out with sterilized water. The first essential to effective therapy is the exact diagnosis of the seat of disease; especially should the differential diagnosis between cystitis and pyelitis be made. For a simple pyelitis four quarts of water is given a day, together with salol. Obstinate cases are put to bed, and a Fezzer catheter left in situ. This failing, exploratory lumbar incision is indicated.

Melichor states that bacterium coli is the most frequent cause of bacteriuria, and also produces acid urine; but this condition might also be caused by urea-decomposing microbes; that bacteriuria may be renal or vesical—in the latter case the prostate sometimes playing an important part as the focus of the infectious substance; that bacterium coli is the microbe most frequently found in cystitis, pyelitis, and suppurative pyelonphritis; that in a large proportion of cases cystitis is combined with acid urine.

THE TREATMENT OF CARIES OF SACROILIAC SYNCHONDROSIS.

WOLFF (Deutsche Zeitschrift für Chirurgie, 49 Bd., 6 Heft, 1898) has never seen the synovial form of tuberculosis of the sacroiliac synchondrosis, the disease always having appeared in the osteal form and usually accompanied by abscesses. The pus commonly forms a gluteal abscess, passing from the anterior surface of the synchondrosis through the larger ischiatic foramen, and sometimes attaining extraordinary dimensions, reaching from the crest of the ilium to the knee. The pus may also follow the course of the iliac muscle pointing in the groin, or may become apparent in the ischiorectal foramen.

The diagnosis of the affection is sometimes extremely difficult, and in the absence of demonstrable pus for months may simulate neuralgia or neuritis. The affection usually begins with pains in the sacrum, often following slight trauma, such as a fall upon the feet, the lifting of a heavy weight, etc. It is probable that such forms of trauma are not causative, but simply render manifest latent processes. Frequently the patients remark, as a first symptom, that putting on their shoes and stockings is becoming progressively more difficult. The pain may increase in severity and become permanent, so that finally walking and even sitting are impossible. The cases characterized by pain are usually those in which the sacrum is distinctly involved. Usually the sacrum is much more extensively invaded than the ilium. When the sacrum is very widely infiltrated the prognosis should be extremely guarded, since a thorough removal of the diseased part almost necessarily implies opening of the dura and thus exposing the patient to dangers of septic meningitis. Moreover, it is difficult, under such circumstances, not to wound the rectal and vesical nerves, in which case there would be consequent incontinence, cystitis, pyelitis, and an ultimate fatal result, sequelae which have occurred in three of the author's cases. Bilateral shooting pains should, therefore, put the surgeon on his guard as to promising too much from operation.
It must be remembered, however, that pain, either local or disseminated, is by no means an invariable symptom of caries of the synchondrosis. Cases sometimes come under observation exhibiting a large abscess unassociated with either pain or disability. An invariable symptom is, however, tenderness on pressure, often elicited by lateral compression of the two iliac bones. A more reliable means of eliciting this tenderness is by pressure made directly over the synchondrosis. The patient is placed in the ventral decubitus; this region, together with the surface of the sacrum, is palpated, and the examination is completed by rectal palpation. This last exploration, in non-suppurative forms of the disease, sometimes gives the only diagnostic sign. Pressure of the finger introduced into the rectum and directed toward the diseased synchondrosis is extremely painful, and usually discovers edema or swelling, the presence of which is determined by a comparison with the sound side. The presence of an abscess is of direct diagnostic importance only when associated with the signs and symptoms already mentioned; since caries of the spine, or practically of any part of the pelvic brim, may cause pus to appear in the gluteal region or in the other regions supposed to be characteristic of suppuration of the sacroiliac joint.

Caries of the sacroiliac synchondrosis is, if untreated, almost certainly fatal, usually from extensive suppuration and amyloid degeneration.

Rest and splinting are means to be employed when there is no abscess formation—that is, in about twenty per cent of the cases. When pus is formed, and in many of the cases treated by rest this will take place, operation is indicated, and this should be timely—i.e., as soon as the diagnosis is positively established—in order to prevent extensive destruction of the sacrum, since this bone is quickly involved. The customary curettage and injection of iodoform are serviceable only in the milder cases—those in which the sharp spoon or the chisel has the good fortune to reach and remove isolated, sharply circumscribed areas of disease. For all well-advanced cases (and this includes those in which an abscess has formed on the inner surface of the sacrum) such operative interference is absolutely futile.

Bardenheuer advises an operation by which he cuts through the gluteal musculature, passes a chain-saw subperiosteally around the ilium, saws it through, tears this loosened posterior piece from its synchondrosis, and then attacks the sacrum with a chisel. Of twelve cases seven were cured; five died—one of shock, one of tuberculosis of the lungs, and three of sepsis. In all these three there were paralysis of the bladder and ascending infection due to cutting of the nerves.

The new method is based on that which Sprengel designed for caries of the pelvis. The incision begins in the middle of Poupart’s ligament, runs in a curve outward over the crest of the ilium, then downward over the sacrum, a little to the inner side of the synchondrosis, and finally follows the course of the sacroischiatic ligament, ending over the tuber ischii. The incision goes directly down to the bone. The muscles of the anterior superior spine of the ilium are separated at their points of attachment, the external lip of the crest of the ilium is cut away from the bone with the resection knife, and the periosteum, together with the external lip, to which it remains attached, is stripped from the outer surface of the ilium. This stripping of the periosteum with the attached muscle is extremely important. A large musculoperiosteal flap is thus stripped down until the gluteal arteries and veins are reached at their points of exit from the ischiatic foramen. Here they are tied and cut through. The iliopsoas muscle is then freed from the inner surface of the ilium, together with the periosteum and the inner lip of the crest of the ilium; the Gigli saw is passed from the ischiatic foramen around the ilium, and this bone is sawed through. By the exerting of a moderate amount of force the posterior part of the ilium is torn loose from its articulation with the sacrum, and this bone is attacked with the chisel and is cut away until only the sound portions are left. The nerves passing through the sacral foramina should be spared. This end is attained by passing a probe in the foramen near which the surgeon is chiseling.

After complete removal of the diseased parts, hemorrhage is stopped and the wound is closed by two layers of sutures. The external lip of the iliac crest is united to the inner lip, after which the skin is sewed, and in the anterior and posterior angles there is inserted a glass drainage-tube. Finally, after the antiseptic dressing, a plaster bandage is applied, enclosing the trunk, from the lower border of the ribs, the thigh and leg of the resected side, and the thigh of the sound
side. Bleeding is very slight. Separation of the gluteal muscle flap is extremely easy when the operation is conducted subperiosteally. As to the permanent disability caused by this resection, extensive since the line of sawing runs from the middle of the ischiatic foramen to a point on the iliac crest just behind its anterior superior spinous process, Wolff states that reorganization of the bone is extremely rapid, and that a man on whom he operated thus in 1895 has been working at his trade as a baker for three years without experiencing any inconvenience.

THE VALUE OF X-RAYS IN SURGERY OF THE NOSE.

Speiss (Revue de Rhinologie, Otologie et Laryngologie, No. 5, 1898) finds that the Roentgen rays afford a new means of obtaining evidence as to the existence and the dimensions of the sinuses of the head, and of the possibility of treating these sinuses by the endonasal route. The author has particularly concerned himself with opening the frontal sinus. Through the nose he drives an electrical trephine into the center of this sinus, controlling the direction which this instrument takes by the fluoroscope. Thus he is able to observe exactly the course of the instrument. The opening, having once been made, can be enlarged until complete drainage is provided for. Cure does not necessarily follow a simple opening. The latter operation must be considered as purely exploratory; the diagnosis having been thus made, it allows the surgeon to practice lavage. The x-rays may sometimes mislead in deciding as to whether or not there exists a frontal sinus, as may also transillumination. Tenderness on percussion over the frontal sinus and on pressure exerted upon the orbital roof at the inner angle of the eye are almost constant symptoms of sinusitis.

THE RADICAL TREATMENT OF HEMORRHOIDS.

Schiff (Medical Record, Dec. 31, 1898) describes an operation for the radical cure of hemorrhoids which in many cases possesses advantages over the operations usually performed. After having thoroughly stretched the sphincter, and plugged the bowel above with a pad of iodoform gauze, the mass or hemorrhoid is seized with a clamp and removed by an elliptical incision, cutting from the cutaneous surface inward and upward, thus leaving the vessels the last part to be severed. As soon as the vessels come into view they are grasped with an artery clamp, and the entire mass is separated from its connection with the bowel. The vessels are then ligated and the mucous membrane and cutaneous wounds are sutured. Usually these sutures are so inserted that the line of union shall be parallel with the bowel. In cases in which there might be a tendency to stricture, or in which the lower bowel is narrow, sutures are passed at right angles to the bowel, so that the cicatrix shall be parallel to the sphincter. In all cases the old rule of leaving mucous membrane between the mass removed must be adhered to. After completion of the suture the iodoform plug is withdrawn. Convalescence requires from three to five days, is unattended with severe pain, and the danger of secondary hemorrhage is minimized.

TUBERCULOSIS OF THE PAROTID GLAND.

Parent (Thèse de Paris, 1898) concludes that tuberculosis of the parotid is commonest in the adult, that it is usually a purely local disease, and is as a rule unassociated with tuberculosis in any other part of the body. The affection begins very insidiously, the patient noticing, perhaps by accident, some swelling of the parotid region. It is unattended with pain and grows very slowly. Exceptionally there is sharp pain about the ear and the orbit, and sometimes a facial palsy. The tumor is hard, at times softened in points, non-adherent. The clinical symptoms suggest tuberculous adenitis, gumma, actinomycosis, or neoplasms. The slow development suggests the diagnosis, which often can be confirmed only by microscopic examination. The sole treatment to be considered is extirpation of the tumor or ablation of the entire gland. The results of this treatment are excellent.

THE TREATMENT OF VESICAL HEMORRHAGE.

Nougès (Ann. des Malad. des Org. Génito-Urin., 1898, No. 8), in discussing the treatment of bleeding from vesical neoplasms, states that the rational and immediate indication is removal of the growth by operation. If, however, circumstances are such that this is impracticable, the bladder must be first freed of its clots either by a catheter of large
caliber or by incision and permanent drain-
age, after which a five-per-cent solution of
gelatin in 7.10 sodium chloride is injected
into the bladder and slowly withdrawn. At
first it is injected in small quantities; later
sufficient of it is forced in to fill without dis-
tending the bladder. The catheter is then
taken out, and the injected gelatin salt solu-
tion is allowed to remain.

REESTABLISHING SURGICALLY THE IN-
TERRUPTED PORTAL CIRCULATION
IN CIRRHOSIS OF THE LIVER.

Wier (Medical Record, Feb. 4, 1898) had
his attention first directed to the subject of
reestablishing surgically the interrupted
portal circulation by a communication of
Drummond and Morrison, who stated that
they had cured a case of ascites due to cir-
rhosis of the liver by simply bringing about
adhesions between the omentum and parietal
peritoneum, as well as between the upper
surface of the right lobe of the liver and the
diaphragm. The method in which they pro-
ceeded was as follows:

The abdomen was opened between the
umbilicus and the pubis. The entire fluid
was evacuated; the abdominal cavity was
carefully dried with sponges and then
scrubbed vigorously, as was also the parietal
peritoneum. The peritoneal covering of the
liver and of the spleen, and the portions of
the parietal peritoneum opposed to them,
were especially scrubbed. Finally the omen-
tum was fastened by sutures across the an-
terior abdominal wall; then the wound was
closed, save at one place, where a glass tube
was introduced into the pouch of Douglas
for drainage. In the one case there was no
improvement, the patient perishing nineteen
months later, after having been tapped sixty-
nine times following operation. In the second
case—a pronounced one—there was appar-
ent return to perfect health.

Talma reported a case cured by three
operations. The first was simply an explor-
atory incision followed by gaping of the
wound for five days, with prolapse of the
omentum, a part of which was cut off, the
rest replaced, and the wound reunited. Six
weeks later, in which time four paracenteses
were made, a second laparotomy was done,
and the omentum stitched in the wound. No
further recurrence of ascites took place, but
the enlargement of the spleen, which reached
to the middle of Poupart’s ligament, contin-
ued. A third laparotomy was accomplished,
by which the lower end of the spleen was
tucked in between the skin and the perito-
neum to facilitate adhesions and venous
intercommunications. One year later the
patient was well, but the liver and spleen
were both enlarged. The case was consid-
ered as a severe acute hemorrhagic Bright’s
kidney with a hepatic complication, which
ended in an atrophic cirrhosis, with its usual
obstruction of the portal vein.

Wier’s case, one of cirrhosis from alcohol-
ism, had been tapped several times at inter-
vals of about a week, two or three gallons
being removed from the abdominal cavity
each time. He lost rapidly in weight. The
liver and spleen were both large—the spleen
twice its normal size. A four-inch incision
was made over the upper third of the right
rectus muscle; the anterior superior surface
of the right lobe of the liver, the correspon-
ding diaphragmatic part of the peritoneum,
and the parietal peritoneum adjoining the
wound, were freely scraped with the sharp
point of a steel hat-pin, and the omentum
was stitched on each side of the wound by
six or eight catgut sutures, the wound being
finally closed by buried layer sutures. Before
this was done a smaller opening, one inch
long, was made above the pubis, to admit a
double perforated glass drainage-tube to the
space behind the bladder, to which was sub-
sequently attached a Cathcart’s permanent
siphon. Compression of the abdominal walls
was accomplished by broad strips of adhesive
plaster. The patient died five days later,
from extensive peritonitis, probably caused
by infection of the drainage-tube.

NARCOSIS BY ETHYL CHLORIDE.

Lotheisen (Archiv für Klinische Chirurgie,
57 Bd., 4 Heft) reports 170 cases of narcosis
by ethyl chloride. The amount required for
each narcosis varied between two and three
draehms. There was a stage of excitement
in thirteen per cent of the cases. Complete
narcosis was developed very quickly and
lasted for from five to ten minutes. There
were no sequelae of note, except that eighteen
cases vomited. There were no accidents.

RADICAL CURE OF SARCOMA OF THE
SPLEEN.

Asch (Centralblatt für Gynäkologie, No. 52,
1898) states that in 1888 he made a collection
of the cases of spleen extirpation, and could
find but two in which the operation was per-
formed because of sarcoma. One operated upon by Billroth in 1884 died three months later of recurrence. The other was operated upon by Fritsch in 1889. This woman lived for six and a half years without any recurrence, and then died apparently of heart disease. In the last ten years the author has been able to find no further case of extirpation of sarcomatous spleen.

A SUBSTITUTE FOR THE MURPHY BUTTON.

Genella (New York Medical Journal, Jan. 7, 1899) offers as a substitute for Murphy's button an instrument that is easy to make, easy to apply, and easy to sterilize. The instrument is a two-bladed forceps, each blade ending in an incomplete ring. Both blades are of the same size and structure, except, as in other forceps, one is female and the other a male blade, for disarticulation and sterilization. A number of forceps with rings of various sizes should be provided.

The modus operandi of the operation is as follows: The abdomen is opened as usual and the diseased or injured portion of the intestine is removed. A hole is then punctured, or a fifth-of-an-inch slit is cut, about a third of an inch from the cut margin of the gut, at a point opposite the mesenteric attachment. An ordinary aspirating needle is the best instrument to use. Holding the handle down the extremity of the incomplete circle of the male or female blade is then inserted into the hole, and by a circular motion, raising the handle up, the incomplete circular part of the forceps is placed inside the gut. The other blade is then inserted in the other gut in the same way. The ends of the gut are now invaginated each into the ring of the part of the forceps which it contains, and the blades are locked and clasped, care being taken not to clasp them too tight for fear of injuring the gut. Often the gut after being thus invaginated refuses so to remain long enough to allow the forceps to be locked, in which case two primary stitches of Monsel's are inserted. But instead of using his window, the stitches are threaded on a needle and passed through the fifth-of-an-inch puncture next to the handle of the male blade. The stitches are then pulled on and the gut ends invaginated until the blades are firmly locked; after which, by pulling on one end of the stitch, both can be removed, as they no longer serve a useful purpose. The forceps having been clamped a row of Lembert sutures secures the gut ends in proper apposition. The forceps are then unclasped until the gut is no longer held. The handle of each blade is then so manipulated that its ring is removed from the intestinal tract. The fenestra in the mesentery and the two little fifth-of-an-inch puncture holes are next carefully stitched up, leaving a simple anastomosis, with nothing foreign left in the intestines.

This operation is superior to Murphy's, since no irritating body is left in the intestinal tract. The instrument is simple and inexpensive, and can be easily sterilized. It is superior to Monsel's invagination, in substituting a fenestra a fifth of an inch in diameter for his fenestra of an inch or an inch and a half. And the Lembert sutures can be made firmer and more regular, without having the gut constantly slipping away.

This instrument is superior to La Place's modification of Murphy's procedure, being simpler and easier to clean. In all other points La Place's instrument is just as good. It is important not to pinch the gut, and not to open the blades too wide when removing the forceps. The cut in the mesentery should not be stitched until the forceps is removed.

A NEW METHOD OF DRESSING COLLES' FRACTURE.

Barnes (Medical Record, Jan. 21, 1899) states that after having used the classical pistol-shaped splints for some years, he was led to adopt the dressing about to be described, which, as far as he has been able to ascertain, is original. The dressing consists of a piece of rubber adhesive plaster, of the proper width and long enough to go a little more than one and one-half times around the wrist, and a piece of roller bandage three inches in width and about one-third of an inch in thickness when tightly rolled. The fracture having been properly reduced by extension from the hand and elbow, the surgeon cuts his plaster of the length already described, and of a width corresponding to that of the lower fragment. The piece of roller bandage is laid upon the palmar surface of the wrist at its ulnar side, extending from a point above and to the inner side of the styloid process of the ulna toward, and slightly pressing upon, the thumb at its inner aspect. The plaster is now firmly applied upon the dorsal surface of the lower fragment, carried firmly and tightly across the palmar surface of the wrist, and the roller bandage brought around the ulna to the dor-
oral surface of the wrist; and while the surgeon with his disengaged hand firmly and strongly supinates the upper fragment, the plaster is carried across this and again across the palmar surface of the wrist to the border of the ulna, when the excess of the plaster is to be cut away and the end firmly applied to the surface. A roller bandage smoothly applied completes the dressing, and the arm is to be placed in a sling. The patient can at any time move the thumb and fingers, and is encouraged to do so to a moderate extent as far as it can be done without causing pain or ache. The object of the piece of roller bandage is to keep the ulna in position and also to preserve the arched formation of the bones of the carpus.

In a series of twelve cases this method has given perfect results in every case. One of the greatest advantages is that the patient so soon recovers the use of the hand and arm when the dressings are removed. If the plaster should prove too tight the pressure may be relieved by cutting with a sharp scalpel a series of buttonholes in the plaster at the points of constriction. If the patient is inclined to embonpoint, the edges of the plaster may be lightly nicked by a pair of probe-pointed scissors. It is well to remove and reapply the plaster some time during the second or third week.

ORTHOFORM IN TOOTHACHE.

HILDRENT (Medical Press and Circular, Dec. 21, 1898) asserts that orthoform immediately and completely relieves the severe pain due to inflammation of the pulp in a decayed tooth. To this end it is sufficient to introduce into the cavity of the tooth a plug of cotton steeped in an alcoholic solution of orthoform. Being absolutely deprived of any toxic properties orthoform constitutes in such cases a simple remedy, and one which can be applied by the patient himself without danger.

SUTURE OF THE ABDOMINAL PARIETES AND SCAR HERNIA.

ABEL (Archiv für Klinische Chirurgie, 56 Bd., 3 Heft) with most praiseworthy industry and perseverance has been able to follow the histories of 665 laparotomies performed in the Zweifel clinics; 586 of these patients he saw himself. As a result of this study he finds that the through-and-through method of sewing—i.e., passing of one thread through the entire thickness of the abdominal walls—is followed by a large percentage of abdominal hernia. The best safeguards against the development of this sequel of abdominal operations are afforded by a careful adaptation of the anatomical structures which have been divided by means of buried sutures, the fascia suture being particularly important, and by the securing of union by first intention.

A CLINICAL STUDY OF WOUNDS OF THE SKULL AND THE BRAIN.

SCHLOFFER has contributed to the Beiträge zur Klinischen Chirurgie a number of interesting cases of injuries to the skull and the brain (abstract in the Münchener Medicinische Wochenschrift), dwelling particularly on the symptomatology and treatment. Among others, there was a case of gunshot wound of the brain, the missile passing obliquely through the cerebral substance, having been abstracted from the side opposite the wound of entrance. This case recovered, but afterward developed epileptic seizures. There was a case of gunshot wound in which the missile was not found; healing took place, and afterward an abscess formed. The patient perished through lobular pneumonia.

There was also a case of gunshot wound in which the missile, entering the mouth, penetrated into the posterior fossa of the skull, and was extracted from that region, after having been located by x-rays. This operation was followed by recovery. In one case of prolapse of the brain, following extensive injury, a plate of celluloid was inserted, the wound healing over it.

Schloffer advocates trephining in cases of gunshot wound of the brain for the removal of splinters which have been driven in, for the purpose of rendering disinfection more effective, and especially to enable the surgeon to check arterial bleeding, and for the relief of pressure when it is denoted by contralateral contractures or palsy. As opposed to more conservative surgeons, he believes that the bullet should always be removed when it can be reached. This is especially urgent when from its position it causes irritation, as evidenced by peripheral symptoms.

SUTURE OF WOUNDS OF THE HEART.

GIORDANO (Riforma Medica, 1898, quoted by Münchener Medicinische Wochenschrift, Dec. 20, 1898) summarizes an article on this question by stating that the greatest speed
is required in the treatment of wounds of the heart; that the opening must be sufficiently large to bring the operative area completely under the surgeon's eye; and that since the operation is one of emergency it must usually be performed with but few assistants. The anterior and lateral surfaces of the heart can be reached from the anterior thoracic region, both left ventricle and auricle from the left side, the right auricle from the right side. For suturing a wound of the ventricle the resection of a single rib, the fourth or fifth, is sufficient. Resection of the sternum is never necessary. When the auricle is wounded it is usually necessary to resect the third and the fourth ribs; and if it is desirable to inspect the whole heart, the fifth also must be resected.

VAGINITIS IN CHILDREN.

The following formula is given in the Revue de Chirurgie of December 10, 1898:

- Oil of eucalyptus, 12 grains;
- White wax, 90 grains;
- Cacao butter, 90 grains.

Make four suppositories.

LOCAL INFILTRATION ANALGESIA.

Barker (The Lancet, Feb. 4, 1899), following Braun's teaching, employs as a local anesthetic a mixture made up of one part of eucaine, eight parts of sodium chloride, and 1000 parts of water.

This he suggests can be used in any amount without danger of poisoning, since the eucaine is only about one-fifth as toxic as cocaine, and is equally efficacious as a local anesthetic. Ten and a quarter ounces of this solution has been injected without ill effect.

In practice, the best way to employ this eucaine salt solution is to have powders made which can be boiled in the proper quantity of water at the time of operation. For injecting this solution, a syringe should be used which holds from one to three drachms, and which has an asbestos piston in a glass cylinder, so perfectly fitted that there is no leakage. To this syringe are fitted either fine needles for the skin, or coarser ones for the deeper parts, one of which is bent for use in cavities. The syringe is filled with the solution heated to a little above the body temperature, and the parts to be operated upon are thoroughly infiltrated, including, if necessary, not only the areolar tissues, but even the muscles and the periosteum. In about five or ten minutes the part thus injected will be in a state of analgesia.

The operation should not be conducted while the patient is fasting. A nutritious meal should be given shortly before. The patient is thus fortified against nervous shock, and, moreover, the sensibility of his skin is lessened. This latter effect is still more accentuated by administering alcohol.

As to the drawbacks of local infiltration analgesia, the consciousness of the patient is certainly one. Thus in people who are highly nervous, and in children, the method will have but a very limited application. Again, there is no motor paralysis. The author has performed under this form of analgesia, during the month of January, three radical cures of hernia, one of abdominal section for acute peritonitis, one wiring of the patella, and a number of other operations. The artificial edema certainly masks anatomical details, and finally the method is time-consuming. It must be remembered that at the best in extensive operations the method does not produce total anesthesia, but only analgesia.

LAPAROTOMY FOR CONTUSIONS OF THE ABDOMEN DUE TO THE KICK OF A HORSE.

Potherat (Revue de Chirurgie, Dec. 19, 1898) concludes that when a man is kicked in the stomach by a horse, especially when the injury occurs after a meal, immediate laparotomy should be performed, even though there are no symptoms of visceral lesion.

He bases this opinion on two cases. The first, immediately after having been kicked, vomited. When he was seen ten hours later his belly was slightly tympanitic, and he complained of severe pain at the umbilicus. The temperature and pulse were normal. The abdominal muscles were strongly contracted. Upon this point—i.e., abdominal hardness—Potherat places weight. Hence he practiced section and found a small intestine torn. The patient did well until the fifth day, when he died of acute peritonitis. The autopsy showed an undiscovered lesion on the posterior surface of the third part of the duodenum.

The second patient was kicked, but did not even suffer severe pain. He was opened, and blood was found in the pelvis. Guided by this, a longitudinal rupture was discovered in the small intestine, involving the serous coats, but not passing completely through the mucous coat. The patient recovered.
Hartmann, in the discussion of these cases, held that abdominal rigidity, not limited to the seat of injury, should always be taken as an indication for immediate operation after an accident of the nature under discussion. He has been thus guided in seven cases, each time finding a lesion. In three others he abstained from operation. They all recovered.

Delorme waits for symptoms. In twelve cases he has intervened but once, and does not regret his conservatism. He has noted abdominal rigidity more or less transitory in the cases which recovered without intervention, and also noted that in the serious cases this contracture was often wanting.

Broca believes that waiting for symptoms may cause fatality. He was called to see one case kicked by a horse immediately after a meal. There were no suspicious symptoms, and the case was treated conservatively. The next day acute peritonitis developed, and laparotomy showed that the transverse colon was completely torn across. The patient died.

Nimier saw six cases kicked in the stomach by horses. All got well. Only one was sectioned. The spleen in this case was torn. Nimier waited for the first symptoms of peritoneal infection. These developed between the twelfth and twenty-fourth hour after the accident. Nimier believes that by thus waiting the results will be quite as good as among patients who are subjected to immediate exploratory laparotomy.

TREATMENT OF VENEREAL WARTS BY RESORCIN.

SILBERMINTZ (Revue Pratique d’Obstétrique et de Gynécologie, vol. xiv, No. 12) has found resorcin the most efficacious means in the treatment of the vegetations which so frequently develop about the genitalia.

If the vegetations be isolated, pedunculated, and surrounded by healthy skin, the growths are covered by a paste made of resorcin mixed with water. This is covered in with a gauze compress, and the application is repeated daily until the vegetations dry and fall off.

In the case of multiple extensive sessile vegetations upon the glans, the prepuce, in the inguinal folds, or upon any of the region subject to these growths, the following preparation is applied:

Flexible collodion, 80 parts;
Resorcin, 20 parts.

Before applying this mixture the growths are dried with alcohol or ether, and not only the warts but the surrounding healthy surfaces are painted with the collodion. When the first coating becomes detached it carries with it the-superficial layers of the papillomatous growth. Two or three applications are sufficient to accomplish a cure. There is left a worm-eaten granulating surface, the irregularities and indentations of which are due to the roots of the papillomatous growth. Cicatrization takes place rapidly under slightly astringent powders.

When the skin is dry and comparatively thick, as upon the outer surfaces of the labia majora, a preparation is used containing 50 parts of resorcin to 100 parts of collodion.

When the vegetations are seen at their very beginning, when they are as yet scarcely visible, the parts affected are dressed with compresses wet in a two-per-cent solution of resorcin. In two or three days the skin hypertrophies entirely disappear. In any case the parts affected are cleansed with boric acid solution and are dressed with small gauze compresses.

TREATMENT OF URETHRITIS BY METHYLENE BLUE.

YOUNG (Toledo Medical and Surgical Reporter, February, 1899) advocates the internal administration of methylene blue in the treatment of acute and chronic gonorrhoea. He employs the following formula:

<table>
<thead>
<tr>
<th>Ingredient</th>
<th>Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Methylene blue, 2 grains</td>
<td></td>
</tr>
<tr>
<td>Oil of sandalwood, 3 grains</td>
<td></td>
</tr>
<tr>
<td>Oil of resin of copaiba, 3 grains</td>
<td></td>
</tr>
<tr>
<td>Oil of cinnamon, 1 drop</td>
<td></td>
</tr>
</tbody>
</table>

Make into one capsule.

One such capsule is given thrice daily. In three or four hours after the first dose the urine is colored a brilliant blue. In addition to this pleasing effect, it is stated that the drug distinctly modifies the severity of the inflammatory symptoms.

THE TREATMENT OF CHANCROID BY ANTISTREPTOCOCCUS SERUM.

MOORE (Klinische Therapeutische Wochenchrift, No. 49, 1898) treated forty-eight cases of chancroid, complicated by bubo, with anti-streptococcus serum, combined with the ordinary antiseptic local applications. Of these only seven suppurated. Five cubic centimeters of the serum was injected in both inguinal regions. When the inflammatory symptoms were not more than forty-eight hours old, an injection of ten cubic centi-
meters was usually sufficient to prevent suppuration. Often when this had occurred serum injections seemed to prevent its extension. In one case of phagedenic ulcer the serum showed not only decided antitoxic powers, since it markedly modified the general septic symptoms, but it also decidedly stimulated the local healing.

---

**TREATMENT OF CARBUNCLES.**

ROSENBAUM (New York Medical Journal, June 11, 1898) claims for the following method of treatment that it is painless, the healing is quicker, and no scar or cicatrix remains. A pad of eight layers of gauze somewhat larger than the inflamed surface is soaked in Thiersch’s solution (acid salicyl. 3 ss, acid bor. 3 iiss, aq. Oij), covered with a layer of ten-per-cent ichthylol ointment, applied to the carbuncle, and held in place by rubber protective, cotton-wool, and a bandage. This dressing is left for two days, after which the cores are found to have separated from their walls. They can be painlessly removed at the next dressing.

---

**CHOICE OF METHODS IN HYSTERECTOMY.**

CUSHING (Annals of Gynecology and Pediatry, October, 1898) considers the following methods of hysterectomy, each of which is or may be preferable in certain cases, so that it is of interest and importance to examine the indications which would cause either one or the other to be chosen in a given case:

1. Suprapubic amputation: (a) Extraperitoneal; (b) infraperitoneal (cervix cauterized and drained; cervix closed without cautery).

2. Total extirpation: (a) Abdominal—vagina open (peritoneum open or closed); vagina closed, choice of catgut or silk; combined operation, by vaginal and abdominal incision; methods of Doyen, Martin, Richelot. (b) Vaginal—clamps (morcellation); ligatures, abdomen drained or closed.

The extraperitoneal treatment of the stump, by pins and the serre-noeud or elastic constrictor, has been abandoned except under unusual circumstances. Nevertheless, it is well to remember that it remains a precious resource as an expedient of emergency, when, by reason of shock or weakness from previous hemorrhage, it is advisable to terminate an operation immediately. In some cases also of Porro’s operation, where the great vessels of the pregnant uterus are a formidable fac-

---

or, where there has been a rupture of the uterus during labor and operation of emergency is performed, this method of treating the stump will always have certain advantages for those who are familiar with it.

The method of treating the stump intraperitoneally by dilating and cauterizing the cervical canal and draining it with gauze has been generally given up, because in cases where there is especial reason to fear infection from the cervical canal it is better to remove the whole cervix.

Careful experiments have shown that the healthy cervical canal is not septic, and the preparation for hysterectomy now universally adopted included thorough cleansing and disinfection of the whole uterine cavity, so that when the opening of the stump is closed by suture it is found safe and preferable not to cauterize it, and thereby a better union is obtained.

If, when the stump is divided, the incision is made quite conical, by traction on the body of the uterus and an oblique incision, there is very little of the cervical mucous membrane left, and there is a flap of uterine tissue in front and behind. A long curved probe is passed through the canal from above downward, the assistant drawing down through the canal a strip of iodoform gauze wet in sublimate solution; this wipes all mucus and secretion from the mucous membrane, including any secretion which may have descended from the uterus during the operation, and prevents any infection of the cervical stump from the vagina after the operation. Even this procedure is not necessary in most cases. The flaps of the cervix are then united with catgut in continuous suture above the mucous membrane of the canal, and, returning, unite the peritoneum over the uterine tissue.

As to the indications for removing the whole of the cervix, or for leaving some of it, the burden of proof seems to be on those who advocate total extirpation, for it prolongs the operation from ten minutes to half an hour, while frequently there is some blood lost before the lateral and posterior vaginal arteries are controlled. It may be added that the field of operation is brought nearer the ureters, and accidents have happened from this reason. It would seem that the opening of the vagina would increase the chance of infection, in spite of the most careful disinfection before the operation, and often when the vagina is short and the abdominal walls are thick or rigid the difficulty
of operation is perceptibly increased. It is claimed that the pelvic floor is injured and the support of the intestines is diminished if the cervix is removed. It is not to be denied that the cervix uteri is the seat of sexual sensation to a considerable degree, and in many women it probably has a part to fulfil in the sexual orgasm, so that it is desirable to leave it intact unless there are indications for its removal. Nevertheless, whenever hysterectomy is performed for malignant disease of any part of the uterus, the extirpation should be total; when the cervix itself is diseased, so that it is enlarged, eroded, or secreting profusely an unhealthy mucus or pus, it is better to remove it; when the uterus is removed with the tubes for tubercular conditions, or for gonorrheal disease which manifestly involves the uterine mucous membrane, so that there is presumably an infectious condition of the secretions, it is better to perform total extirpation, especially as in these cases it is often essential to provide for drainage. The same necessity for drainage may be a reason for total hysterectomy in cases where subperitoneal growth of fibroids has lifted up the peritoneum and left large raw surfaces.

If it is decided to remove the whole of the cervix, instead of amputating it, the incision is carried down at each side, keeping close to the uterus, and pinching the lateral cervical arteries, until the vagina is opened; or with a knife a median posterior incision may be made, cutting against the cervix, until the vagina is opened; or the same end can be reached by passing one blade of a pair of scissors into the cervix and cutting through it posteriorly until the posterior cul-de-sac is entered. When the whole cervix has thus been removed, the operator has the choice of three methods: either (1) the vagina may be left wide open for drainage; (2) the peritoneum may be closed and the vaginal raw surfaces may be left open; or (3) the vagina and peritoneum may be wholly closed.

The method of election is that of closing the opening in the vagina with a continuous catgut suture, and afterward uniting the peritoneum with another continuous suture of catgut, so that there is an unbroken line of union from the free border of one broad ligament, across the pelvis, covering the stumps of the arteries and the line of union of the vagina, to the free border of the other broad ligament. When this is completed there is no raw surface whatever in the pelvic cavity, there is no need of drainage, and the convalescence is astonishingly smooth and painless. It makes it easier to unite the peritoneum smoothly, burying all raw surfaces if, instead of applying mass ligatures, the broad ligaments are held by the fingers when severed, seizing and tying each artery as it is cut. Of course, if it is desired to show in how small a time the uterus can be removed, the arteries will be at first secured with catch forceps and only tied after the uterus has been removed. Sometimes the difficulties of the operation are such that this is the only practicable method, but it is better to tie each artery when it is cut, for the time must be spent, in any case, before the abdomen can be closed, and there is no real advantage in removing the uterus in a given number of minutes, if the whole duration of the operation is not thereby diminished. When the vagina is cut open, it should be sewed together at once, being held together meanwhile by double tenacula forceps, so that the chance of infection from this source is minimized.

It is indispensable that in the preliminary cleansing of the vagina and uterus all septic material shall have been removed or sterilized; but, although this is easy to say, it is not always accomplished satisfactorily. In foul or suppurating cases it is well, after curetting and washing out the uterus with sublimate solution, to pack the cavity with gauze, and even to sew up the cervix with a few stitches, so that afterwards when the uterus is handled it shall not discharge an infectious secretion into the vagina. This can be done by an assistant so that the operator may keep his hands clean.

This brings us to the consideration of the question whether it is not well to proceed, after cleansing the vagina and uterine cavity, to the separation of the vaginal tissues from the cervix and the ligation of the uterine arteries from the vagina—in other words, to the method known as the combined operation. In cases of fibroids the finished surgeon will never have any difficulty in performing the whole operation from the abdomen. In the exceptional cases where a huge fibroid polyp has been extruded and the thick pedicle passes through the os uteri, it is better to tie and cut the pedicle, pack the uterine cavity with gauze, sew up the os, and then proceed to the abdominal operation as usual.

In cases of pyosalpinx or other obscure conditions it is not well to complicate matters by performing an important part of hysterectomy from the vagina, when on open-
ing the abdomen it may be found that the uterus with the appendages on one side may be saved, or that it may be unnecessary or inconvenient to remove the whole cervix.

In certain cases of cancer of the cervix, however, it may be a great advantage to remove all the tissue which is apparently diseased, before opening the abdominal cavity, if it is thought preferable to finish the operation by celiotomy.

The rule of all finished hysterectomy, either abdominal or vaginal, should be to close the wounds entirely, unless there is a positive indication for drainage or pressure packing.

It remains to consider the methods of Doyen and Martin, in which in the beginning of the operation the posterior vaginal forinx is opened from the abdominal side, the cervix seized and dragged upward, the broad ligaments are divided while compressed by the fingers of assistants, each artery as it is cut being seized and tied afterwards with pressure forceps. Martin ties the broad ligaments before opening the posterior vaginal vault. Richelot’s method is somewhat similar, except that he separates the bladder from the uterus first and makes the incision between the bladder and the cervix, seizing the latter and drawing it up through the wound.

These methods, in simple cases, are rapid and showy, especially in the hands of their distinguished authors, who can make any method of operation seem easy and admirable. They are all outgrowths of the combined operation, by which a part of the operation was done through the vagina—in the case of the French operators, by the introduction of clamps from below, after the vagina was opened from above. They were evolved as a means of operating without the disadvantage of the Trendelenburg position, and for the convenience of an operator standing or sitting between the legs of the patient.

This brings us to the consideration of the relative advantages of abdominal and vaginal hysterectomy.

The advantages claimed for the vaginal method are: less danger of hernia, absence of cicatrix in abdominal wall, less time spent in operation, and less shock.

On the other hand, the abdominal operation has solid advantages which are founded on great principles of surgery and can never be shaken; for it gives greater certainty of diagnosis, greater facility in work by sight, the possibility of recognizing and overcoming unforeseen complications, greater security against wounding intestines and ureters, better control over hemorrhage.

There are certain special considerations which may further influence us in the choice of the method of removing the uterus, such as the age and physical condition of the patient, the amount of fat in the abdominal wall, the caliber of the vagina, the space between the pelvic bones, the preference of the patient, or even the possibility of obtaining consent to a necessary operation, which cannot be obtained if the abdominal wall must be incised.

The conditions, then, which would indicate the choice of the vaginal method with the use of clamps are: First, inflammatory conditions where the presence of pus in large amounts is certain, and the weakness of the patient is such that an abdominal operation would be probably fatal; in other words, where the operation is for the evacuation of pus in the pelvis, the removal of the uterus being incidental, if found to be necessary. Secondly, when the patient is old or weak, and the abdominal walls are very thick, while the vagina is capacious and the uterus freely movable, so that the vaginal operation promises such a saving of time that it seems preferable. Under favorable conditions it can be done in ten minutes or even in half that time, and in some cases this is of real importance. Thirdly, in cases of cancer of the cervix, when the conditions make it undesirable to close the opening in the floor of the pelvis, and the abdominal operation seems to give danger of sepsis.

Except under such rather exceptional circumstances, if vaginal hysterectomy is to have any standing in the present state of surgery, it must be as a very finished procedure of a very finished operator, and it must have a technique which will compare with the abdominal method.

The operation should comprehend the same improvements which have made the abdominal operation so perfect—that is, the vessels should be secured with catgut ligatures, the peritoneum should be accurately brought together, covering all raw surfaces, and the vaginal wound should be united, preferably with catgut, in such a manner as to bury the stumps of the broad ligaments, and to give a linear cicatrix, which may be expected to heal by first intention. While aware that it is possible to remove the uterus without using any ligatures, and without cutting the uterine arteries, yet this does not seem a safe and surgical method, and if the appendages are to be removed also, the absence of the
ligatures becomes too risky to make it a practical procedure. Supposing, therefore, that the ligatures have been applied and the uterus removed, we should try to do what we would do in operating from above—that is, we unite the anterior and posterior peritoneal layers of the broad ligament on each side, from the ovarian down to the uterine artery, with a continuous catgut suture. Then stitches can be passed through the vaginal walls and the peritoneum in such a way that both the peritoneal and mucous surfaces are accurately united, while at the same time the raw surfaces at each side are included so that there will be no oozing. If drainage is thought to be desirable, a small roll of gauze may be left in the center of the incision, instead of closing in completely.

Performed in this way, vaginal hysterectomy has a standing in favorable cases in comparison with the abdominal operation, but the admirable results obtained by the latter method leave little room for the former.

THE TREATMENT OF FALLING OF THE HAIR BY SIMPLE IRRITATION.

Jacourt (La Presse Médicale, Dec. 19, 1898), acknowledging that irritation must form the basis of all successful treatment, directed toward making the hair grow, holds that this irritation should be intermittent rather than constant, and should not be carried to the stage of exudation—that is, it should stop at the point of producing simple hyperemia.

Personally afflicted with falling of the beard, he began treatment by making repeated firm pressure with the bristles of a stiff brush upon the bald area. In a few seconds the skin became red and warm, and this effect lasted from thirty to fifty minutes. The treatment was repeated night and morning until the part became distinctly tender. In four months the bald spot was entirely covered with hair.

Other patients on whom this treatment has been tried have experienced the same benefit, the treatment in their cases being repeated sometimes four to six times a day. The irritation should never be carried to the exudation stage. Together with this form of irritation the author suggests a vigorous friction with a dry brush over the whole area, and holds that by this treatment not only can baldness be prevented from appearing, but can be cured after it has developed.

The brush should be kept perfectly clean, since it produces many breaks in the epidermis, sometimes even causing slight bleeding.

GENERAL INFECTION OF URETERAL ORIGIN.

Rendu (La Presse Médicale, Dec. 19, 1898) reports that forty-eight hours after catheterism there developed general staphylococcus infection so severe that when the patient was taken into the hospital he appeared to be suffering from either supplicative meningitis or adynamic typhoid fever. This condition of general intoxication lasted five days, during which period the predominating symptom was high temperature. There then followed a period marked by the formation of multiple abscesses, located in the subdermic and in the cellular and aponeurotic intermuscular tissue. Thirty-eight such abscesses developed in less than a month and were successively opened. This led to extreme emaciation and muscular atrophy. Slight endocarditis developed, followed later on by hemorrhagic nephritis, due no doubt to the irritation incident to the eliminative toxins. This nephritis occurred thrice during a month, but in spite of it the kidneys remained competent. A true polyuria combined with diaphoresis accomplished the complete elimination of the poison in about two months.

The treatment in this case consisted in the application of baths and lotions, and a milk diet during the early stages of infection. Later, whilst the patient was suffering from hemorrhagic nephritis, tannin seemed to be distinctly serviceable.

A USEFUL METHOD OF DEALING WITH SURGICAL INSTRUMENTS.

Hodgson (Intercolonial Medical Journal of Australasia, Oct. 20, 1898) finds that steel, nickled, or silvered instruments, after cleaning with soap and water, may be sterilized by boiling in a strong solution of washing soda. In this solution they may be left indefinitely, remaining bright, unaffected, and sterile.

Instruments required very promptly for use should be left, after boiling, in a strong solution of caustic soda, from which they may be removed as required. By this means they are not handled before use, and can be used without a second boiling with impunity.

A useful fact is that instruments soiled, as
is a guillotine after use, may be left indefinitely in a strong solution of soda, the only effect being to clean the instrument. Another, that instruments may be removed from soda solutions, and allowed to dry by atmospheric action, without rusting. For many operations weak soda solutions are useful for holding the instruments, instead of the usual corroding carabolic solutions.

THE DEFORMITIES AND SURGICAL AFFECTIONS CAUSED BY WRONGLY SHAPED BOOTS AND SHOES.

JACKSON CLARK (Medical Press and Circular, Sept. 7, 1898) thus enumerates the chief deformities that are contributed to by badly shaped boots and shoes: (1) Hallux valgus; (2) hammer-toe; (3) flatfoot; (4) non-deforming clubfoot; (5) metatarsalgia, or Morton's disease; and with these deformities must be mentioned other common surgical conditions, e.g.: (6) corns; (7) in-pressed toenail. The latter two conditions may be briefly noticed first.

A corn is the result of abnormal pressure on the skin—frequently the result of badly shaped boots—and the removal of abnormal pressure is followed by the disappearance of the corn. If every one wore properly shaped boots the occupation of the chiropodist would be gone. Corns are sometimes symptomatic of more serious surgical conditions. Thus in hallux valgus a callosity may form over the prominent head of the first metatarsal bone; in hammer-toe over the head of the first phalanx, or tip of the toe; in metatarsalgia, due to sinking of transverse arch of the foot, a corn on the sole of the foot opposite the head of the third or fourth metatarsal bone is of frequent occurrence. In such conditions nothing short of removal of the deformity will cure the corn.

In-pressed toenail results from wearing badly shaped boots, which press the skin against the edge of the nail of the great toe, causing ulceration. The nail is purely passive—the boot is the active agent. The term "ingrowing toe-nail" implies perverted growth on the part of the nail, and this in turn has suggested avulsion of the nail or part of it as proper treatment of this condition. This operation is never required. When there is separation of the nail from its bed, a small piece of soft thin linen covered with carbolic ointment should be packed under the nail and between the surface of the nail and the fold of skin. If the condition resists patient trial of this measure the toenail may be removed and its matrix destroyed. If the latter step is not thoroughly carried out the "hypertrophy" will recur when the nail is reproduced.

Bunion, the commonest of all deformities in boot-wearing communities, is due simply to pressure of the boots pointed towards the central line of the foot. In young children tight socks will sometimes give rise to the same deformity. In the production of this as of other deformities, the effects of pressure tell more rapidly and to a greater degree when the bones and ligaments are softened, as in osteoarthritis. Pathologically the condition is a subluxation of the first phalanx and sesamoid bones outwards. In slighter grades of the affection displacement is easily corrected by slight pressure. In such cases, if proper boots and shoes are worn and the joint is manipulated twice a day, deformity will sometimes correct itself. In more severe cases a splint must be worn at night, and the toe kept in proper condition by some means or other during the day also. For nighttime a lever having a broad, well-padded fulcrum about the middle of the first metatarsal at the inner border of the foot is more effectual than the well known bunion-spring. For day use the same contrivances can be, in some instances, worn inside the boot, but each case must be studied and treated on its merits. Sometimes Sayre's plan of placing a cap of leather over the great toe, and attaching to the inner border of the base of this cap a band which is carried above the heel to the outer border of the foot, where it is attached by elastic insertion, will answer. The idea of providing a separate stall for the great toe appears to have originated with Fowler, who describes a boot with a septum consisting of a double layer of calf leather between first and second toe. Such a boot requires a special last. A similar idea has been embodied in the "toe-post." Many patients find the latter too rigid for comfort. The fact that wearing sandals is an efficient preventive of hallux valgus suggests the use of sandals as a curative measure. A stiff sole-plate with slots for tapes, by which the toes are retained in good position, is often the best appliance. If made of stiff thin leather it can be worn inside an ordinary stocking; if made of metal it must be applied over a digitated stocking, and worn inside of the boot.

In all cases of severe hallux valgus there is an obstacle to reduction of deformity, due to
the presence on front of the head of the metatarsal bone of a groove into which the inner edge of the base of the first phalanx fits. In such cases in order to remove deformity it is necessary to open the joint and chisel off the inner part of the head of the metatarsal bone. After this operation the toe is easily straightened, but patient after-treatment is required to prevent relapse.

Hammer-toe is usually associated with hallux valgus, and is generally a secondary effect of this condition. Anderson considers it to be analogous to the corresponding contraction sometimes observed in fingers, and refers it to primary want of growth on the part of the lateral ligaments of the first interphalangeal joint. That this may sometimes be the case I am ready to admit, but in the majority of cases the origin is as stated above.

In slight cases of hammer-toe the use of a plantar splint of thin metal covered with leather and fastened to the foot by tapes, and to the toe by a segment of the finger of a glove, will suffice to cure the condition. In more severe cases the lateral ligaments require division. When the skin is greatly retracted the head of the first phalanx may be excised. A very common treatment for this condition is amputation. This operation is rarely justifiable. In cases where the condition is due to hallux valgus, the removal of the second toe makes the former condition worse and renders its successful treatment impossible. In some instances one of the outer toes is deformed from compression of boots.

A severe neuralgia starting generally near head of third metatarsal bone is due to sinking of transverse arch of foot. Its dependence on badly shaped boots is in some cases evidenced by the fact that the patient only suffers when a particular pair of boots is worn. In other cases the condition appears to be due to osteoarthritis. In severe cases excision of the head of the metatarsal bone is required.

It would be wrong to suppose that every case of flatfoot is due to wearing badly shaped boots. This is, however, one factor in the production of flatfoot that is present in cases of hallux valgus. The outward displacement of the first phalanx of the great toe entails some outward shifting of the tendon of the flexus longus hallucis, and so weakens the support of the inner arch of the foot. The frequent combination of flatfoot with hallux valgus supports this view.

Reviews.

This book its author states is introduced to the profession because of the absence of any manual defining the distinctive features of railway injuries and their proper management. There is no effort made to treat other varieties of injuries nor to enter into detailed consideration of any, but rather to give concise, practical directions for handling the everyday cases that are met with.

The author in his introduction makes some claim for railway surgery as a specialty, and defines as a railway surgeon one who makes a special study of the distinctive features of railway injuries and their appropriate treatment.

The first chapter is devoted to history, statistics, and general considerations. It is interesting to note that there are more than 250,000 miles of railway in the United States, and that in the last year there were over 6,000 people killed, over 36,000 injured—sixty-five every hour of the day and night. The mechanism of injury by coupling is described, also that dependent upon being run over. Attention is called to the fact that in fast-train injuries devitalization extends wide of the immediately crushed part; this, it is stated, is due to plugging of the large artery by a coagulum of blood.

Emergency cases, preparation of materials, sterilization, and anesthetics are all discussed. Chapters are devoted to cuts, burns, bruises, scalds, dislocations, fracture of the skull, fracture of the extremities, etc. Special attention is given to amputation, its indications, and its proper performance. Among other subjects considered are traumatic neurasthenia, jurisprudence in railway surgery, examination of employees, and car sanitation and disinfection.

The book is extremely readable, and though the author has not made out a case for railway surgery as a specialty, he has certainly given a very clear exposition of railway injuries and their proper treatment.

**THE TREATMENT OF DISEASE BY PHYSICAL METHODS.**
By Thomas Stretch Dowse.
Bristol: John Wright & Co., 1898.

This book is in reality devoted to a very full consideration of massage and electrotherapeutics, though its title might suggest that it covered a much wider field. Considering the subjects of which it has to treat, it
seems unnecessarily prolix and involved; and though it no doubt shows that the writer has devoted much time and study to his specialty, it does not tend to give the earnest searcher for the practical application of medical truth much help without what would seem to him an unnecessary amount of digression.

Among the headings of chapters are to be noted the Weir Mitchell Treatment of Neurasthenia, and the Nauheim or Schott Treatment in Diseases of the Heart.

**Progressive Medicine.** A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Vol. I.

The following extract from the Preface shows the scope of these volumes:

"A somewhat intimate acquaintance with medical literature for a considerable period of time has convinced the editor of this publication that even if one has brought to him weekly the best medical literature of the world it is impossible to keep up with it in the sense of grasping its details and assimilating its really valuable practical facts in such a way that they can be applied at the bedside."

"Original researches, disquisitions, records of epoch-making cases or discoveries come to one so fast and so voluminously that a life's work could be found by the physician who attempted to study all the views presented to him. The state of the progressive medical man of to-day is that of a man who while hungry for food has thrust upon him such a mass of pabulum prepared in so many forms by so many cooks that it is possible for him to get but a taste of many dishes from which he might obtain much pleasure and strength if he but knew their real value and design. Often the technical appearance of an article staggers his mental digestion, and he casts it from him as being too difficult a morsel for him to assimilate.

"There are at the present time numerous 'Annuals' or 'Year-books' published with the object of recording in condensed form the greater part of the medical literature of the year, but in nearly all of them the process of 'boiling down' has been practiced without first sifting the useful from the useless, with the result that the physician has presented to him a mass concentrated, it is true, but so varying in quality that the good can only be separated from the bad by a process as difficult as that needed for the utilization of the crude material. What the busy physician needs to-day is a well-told tale of medical progress in all its lines of thought, told in each line by one well qualified to cull only that matter which is worthy of his attention and necessary to his success. He needs an article which can teach him all that the master of a specialty knows of the year's work, and he does not need an immense quantity of material which, however interesting it may be from its novelty, possesses no intrinsic merit.

"It is with the object of presenting such readable and useful material that these volumes are published, and every contributor to the pages of Progressive Medicine has been asked to say what he has to say in narrative form, and, equally important, to place his hallmark on the text, so that it will be a story which bears a personal imprint and will express not only the views of the authors cited, but the opinion of the contributor as well. The volumes contain personal narratives of medical advance, and this characteristic greatly increases their interest and value."

**Diagnosis by the Urine; or, A Practical Examination of Urine with Special Reference to Diagnosis.** By Allard Memminger. Second Edition. Enlarged and Revised. Illustrated.

This is a small octavo volume of a little over 100 pages dealing with the subject of urinary analysis, and covering ground which is already covered in many other little handbooks of this type. It is typically a work which can be placed in the hands of medical students while learning practical urinary analysis, and it will give the practitioner a good idea of the common methods which he should employ for this purpose. It is not, however, as complete and thorough as some other works of the same character.

**A Handbook of Obstetric Nursing. For Nurses, Students, and Mothers.** By Anna M. Fullerton, M.D. Fifth Revised Edition. Illustrated.

Dr. Fullerton's little manual of a little over 250 pages is printed in an attractive form and contains first-rate information, not only for the class of persons named in its subtitle, but also for many physicians who do not know as much as they should concerning the minute management of obstetrical cases, and who have not under them nurses who have received hospital training of this character.

Towards the close of the book a chapter is devoted to infant feeding and to the ailments of early infancy.
Philadelphia: W. B. Saunders, 1899.

There are few books dealing with special realms in medicine which are sufficiently popular to attain to the dignity of a third edition within a period of a little less than seven years, the more so when it is recalled that a supplementary edition of the first was published. As with most books, each subsequent edition of Dr. de Schweinitz’s work has been an improvement over its predecessor, and his care in the revision of the text is only equaled by the care with which he has controlled each scientific statement. In the present edition this repeated revision of the text has presented us with a clear, concise, and readily read volume, dealing with all practical points in connection with ophthalmological practice. New matter covering a number of interesting points has been introduced, of which perhaps the most important are the use of the Roentgen ray in detecting foreign bodies in the vitreous, and those portions of the text which deal with the microorganisms which infect the eye. Other chapters have been largely rewritten, and illustrations designed to still further elucidate the clinical portion of the text have been introduced. It goes without saying that this edition, as did its predecessors, shows on every page not only intimate acquaintance with clinical ophthalmology, but also that its skilful author is thoroughly in touch with the best and latest ophthalmological literature all over the world. On the other side of the Atlantic Swanzry and Nettleship have divided the honors in being the authors of popular handbooks for ophthalmic practice, but in this country Dr. de Schweinitz’s book seems to be facile princeps, and will doubtless continue to be so.

THE MEDICAL NEWS POCKET FORMULARY FOR 1899.
By E. Q. Thornton, M.D.

This pocket book is intended as a companion to the Medical News Visiting List, and takes up about the same space in the pocket as does that publication. In it the names of diseases are arranged alphabetically, and under the name of each disease are printed a number of formulae which Dr. Thornton believes to be particularly efficacious. After each formula are given the indications for its definite and direct use. As the author of this formulary is not only a physician in active practice, but also a graduate in pharmacy, he has utilized his medical and pharmaceutical knowledge in such a way as to prevent incompatibilities, and to pick out particularly efficacious prescriptions, and what is perhaps more important, to define those cases in which drugs should and should not be employed. The volume opens with a dose list, a list of poisons and antidotes, and similar interesting material; and to those physicians who are wont to resort to this sort of an aid in prescription writing, we can cordially commend it.

ANNUAL AND ANALYTICAL CYCLOPEDIA OF PRACTICAL MEDICINE. By Charles E. de M. Sajous, M.D., and 100 Associate Editors, assisted by Corresponding Editors, Collaborators, and Correspondents. Freely Illustrated. Volume II.

It will be remembered by our readers that the first volume of this Analytical Cyclopaedia appeared a little later than this last year, and that it extended in alphabetical progression to the inclusion of “Bright’s Disease.” The present volume extends from “Bromide of Ethyl” to “Diphtheria,” and is compiled in a manner identical with that of its predecessor. As is evident from what we have said, these volumes are designed to come out each year until the alphabet has been completed. They do not deal, as might be imagined, solely with literature during the past year, nor do they consist in exhaustive encyclopedic articles detailing everything that is known of value about the subjects of which they treat; they are rather abstracts and reviews of literature for the past few years, in some instances papers being quoted which were published as long ago as 1893, and abstracts being made from editions of standard text-books which were published in 1894, since which time a number of newer editions have appeared, as for example, in the case of H. C. Wood’s Therapeutics, 1894; Biddle’s Therapeutics, 1895; Hare’s Therapeutics, 1894.

As we stated last year, the great difficulty with this method of publication is that by the time the last volume is issued the information in the first volume must be comparatively behind the times, although on the other hand it is to be remembered that Dr. Sajous’ wide editorial experience has enabled him first to obtain competent assistants, and second, to weed out from the manuscripts submitted to his supervision material which he thinks devoid of interest to the medical public.

We naturally look with interest to see how thorough the review of current medical litera-
ture has been, and we are sorry to notice the omission of a number of papers which are distinctly notable in their character, either because they mention new matter, or else because they were summaries of the subject producing valuable conclusions and affording valuable information to the medical public. Nothing is said, for example, under the use of calcium, of the use of calcium chloride for the purpose of combating hemorrhage, and in the discussion of the ill effects of the bromides a considerable portion of the recent literature upon this subject is ignored. On the other hand, some of the collaborators have evidently taken great pains to make their departments as complete as possible. While the book is not copiously illustrated, the pictures which it contains are unusually well done, and the colored lithograph showing an eruption of the skin produced by bromide of potassium is one of the best lithographs that we have seen made in this country or abroad.

As a reward for his unfailing industry and desire to advance the cause of medical science, we trust that the medical profession will receive this and the following volumes with the enthusiasm which the editor's labors deserve.

Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFIRD, M.A., M.D. OXON., M.R.C.P.
LOND.

The discussion on "Pseudotuberculosis" at the Pathological Society of London drew a full house. Dr. Sims Woodhead in opening commented on the unsatisfactory character of the term "pseudotuberculosis," which had been employed from time to time by different observers to cover such a variety of lesions. He referred to a series of cases which had been detailed in the Report of the Royal Commission on Tuberculosis, in which the naked-eye appearances must unquestionably have led to the diagnosis of tubercular disease but for the negative evidence afforded by the microscope; these were associated with a variety of microorganisms quite distinct from the tubercle bacillus. He had also seen small glistening pearly nodules produced by strongylos filariae in the lungs of sheep included among pseudotubercular lesions. The microscope showed that the nodules consisted of coils of nematode worms surrounded by proliferating connective tissue cells. Professor Muir, of Dundee, had described no less than six forms of pseudotuberculosis in birds. Then, again, in many museum specimens it was clear that cases of actinomycosis had been gathered up into the category of pseudotubercular lesions. Professor Boyce had rescued from this appellation the mycotic condition of the lung due to aspergillus, which Kottjar had described as "aspergillar pseudotuberculosis," but which Boyce termed "aspergillo-pneumonimycosis." The confusion was still further increased by some observers describing "a pseudotuberculosis bacillus" resembling the tubercle bacillus in its morphology and staining reactions, but not associated with the occurrence of pseudotubercular lesions. The position was this: on the one hand they had organisms of pseudotuberculosis which had the morphological and staining characters of the true tubercle bacillus, but which pathologically appeared to be widely separated from it; whilst on the other hand they had a whole series of lesions which presented certain superficial resemblances to tubercle, but which were not induced by the action of the tubercle bacillus. It was very difficult to say what typical tubercle is, seeing that the forms of histological lesion associated with tubercle are so manifold. There was not sufficient evidence to justify the accepting of "pseudotuberculosis" as a pathological entity. It was well to be precise in the use of the term "tuberculosis," and to regard the presence of the tubercle bacillus as the essential factor; on the other hand, it would make the position much clearer if the term "pseudotuberculosis" were rejected altogether, and an effort made to refer to their proper place the essentially distinct lesions grouped under this inappropriate name.

At the Edinburgh Medico-Chirurgical Society Dr. McBride reviewed the whole treatment of ozena, and alluded specially to the method of treatment by cupric electrolysis. The therapeutic principles which had chiefly found favor were: (1) Destruction of the transformed mucous membrane by the curette and by other methods. (2) The application of stimulating and irritating remedies; palliatives had perhaps been most efficacious. The electrocautery had been used in some cases with good effect; "vibratory massage" had been applied to the nasal mucosa by means of a probe capped with wool and made to rotate rapidly either by a manual or electric motor. The objection to this latter mode of treatment was that it occasionally pro-
duced hypertrophy of the mucous membrane. (3) Efforts had been made to secure freer drainage by widening the nasal fossae by obturators and by other means. On the whole antiseptic injections failed to relieve the fetor, and glycerin had failed to relieve the extreme dryness of the mucous membrane. The discovery of a modified form of the Loeffler bacillus among many other organisms in the nose had suggested the employment of the diphtheria antitoxin, and one enthusiast recorded no less than sixteen out of thirty-two cases so treated. Dr. McBride himself had had some encouraging results with cupric electrolysis. Of eight cases, four were practically cured and had remained so for periods of eighteen months or more; the remaining four had been so recently treated as not to be adduced in evidence. Anesthesia was obtained by cocaine, and the current used varied from three to ten milliamperes. The copper needle was attached to the positive pole and was inserted into the inferior or middle turbinated bone, while the platinum or steel needle was inserted into the septum. The procedure was attended by little or no pain, either at the time or subsequently. He hesitated whether to attribute the beneficial effects produced to the copper salts or to the electricity. In the case of relapse it was desirable to repeat the treatment each six months so long as there was any prospect of betterment. Dr. Logan Turner remarked that the treatment was obviously not bactericidal, as the same organisms flourished in the nose after as before; he was inclined to look upon it as some sort of trophic influence, seeing that both nostrils benefited even when the electrolysis had been confined to one. He fancied that the antiptheretic serum exercised a similar stimulant effect locally, and led to the extrusion of crusts.

At the Medical Society of London, Watson Cheyne presented two cases of coxa vara, showing the result of division of the femur below the trochanters. The object of the operation had been to correct the eversion of the leg so that the patients might be able to walk. This form of operation seems to be preferable in young children rather than the method of removing a wedge-shaped piece of bone from the neck of the femur—a procedure which has produced very good results in adults. In children the neck is so short that the operation is one of very great difficulty, and moreover there is more than a little danger of permanent interference with the growth of the bone. The result of the operation was to restore complete usefulness of the limbs, but a totally unexpected result had been also noted in the arrest of the progress of the deformity in the neck of the bone. The operation is given in detail in the Transactions of the Clinical Society, 1893. An incision was made on the outer side of the thigh at the upper part, and the femur, having been exposed and cleaned, was divided transversely across by a saw a little below the trochanters. The foot and leg were then forcibly inverted till the normal degree of complete inversion was obtained, and being held in this position while the trochanters were pushed forward, a perforated oblong aluminum plate was placed over the femur opposite the line of division, and nailed on to the two fragments by tacks which had been nickeled. The object of this was to prevent rotation outward of the limb during the union. The limb was put up in the inverted position, and the wound healed by first intention. The leg was afterwards put in a fixed apparatus for several weeks. Previously to the operation the boy could neither stand nor walk, but now was able to walk quite well. In neither this nor the other case shown had any operation been undertaken on the second leg, but it was remarkable how both legs had benefited by the correction of the one. Why the deformity of the neck of the bone should have been arrested is not obvious. Mr. Cheyne made two suggestions to explain this: (1) That the process of repair and consolidation of the bone around the point of fracture may have extended upwards into the neck of the bone, and led to consolidation and arrest of the softening process which was leading to the curvature; (2) that the branches of the nutrient artery to the neck of the bone were divided in the operation, and as a result of diminished vascularity consolidation of the neck may have been hastened. Mr. Jackson Clarke mentioned several cases in which he had obtained good results without operation by means of apparatus devised to keep the foot forward and to take the weight off the hip.

The National Association for the Prevention of Consumption and other forms of Tuberculosis has set to work in right earnest to sweep away the reproach leveled at our nation by no less an authority than Sir William Broadbent at the meeting at Marlborough House, that in this matter we are "behind the world." The Association has followed not a little in the footsteps of our American brethren, who in this as in many
other branches of preventive medicine are well ahead of us. The methods of the Association are summarized as follows:

1. The education of public opinion and the stimulation of individual initiative by means of: (a) a central office for the collection and distribution of information as to modes of diffusion of tuberculosis and measures of prevention; (b) the circulation of pamphlets and leaflets setting forth in plain language the results of scientific investigation of the above points; (c) public lectures by men approved by the Council, and addresses at congresses and other public gatherings; (d) cooperation with other societies having for their object the promotion of public health; (e) the cooperation of the public press; (f) periodical congresses and the issue of an annual report; (g) the promotion of the establishment of open-air sanatoria for tuberculous patients.

2. The influencing of Parliament, county councils, boards of guardians, chambers of agriculture, and other public authorities on matters relating to the prevention of tuberculosis.

3. The establishment throughout the kingdom of local branches of the Association, which are affiliated with the central office on payment of one-fifth of subscription of membership. Secretaries of branches are supplied with all literature at cost price. Leaflet No. 1 is already in circulation in hues of green and pink, which invite attention.

A few days since we were enabled to show at the Clinical Society of London a case of myositis ossificans, in which there were present some features of great interest; these it was possible to demonstrate by means of skigrams. The congenital condition of the great toes, which in several previously recorded cases has been described as hallux valgus, was shown to be in this case at any rate quite another condition. There was synostosis of the metatarsal bone with the first phalanx, and to compensate this deformity an outward throw of the last phalanx underneath the second toe. In the thumbs there was a condition of microdactyia with rigidity; the rigidity was due to osseous union of the first and second phalanges to each other, while the shortness was mainly due to stunting of the metacarpal bone and not to general shortening of all the bones. For the rest the case, both in the clinical history and in the localization of the bony growths, was very much a replica of the historical cases of the disease already described.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Dr. Plicque, of Paris, has published in a recent number of the Presse Médicale an article on the treatment of "ictère grave." This disease, as the author states, is undoubtedly the most dangerous infection known. Some primary cases are followed by death in a few days. When the disease supervenes as a secondary condition subsequent to, for instance, a severe case of syphilis, cirrhosis, or cancer of the liver, the affection in itself is not so much the real cause of gravity as is the primary disease. However, leaving aside these very severe forms, an active therapeutic intervention is often beneficial and leads to the best results. A major indication is the renal condition. Elimination of all toxins should be favored by a milk diet, plenty of liquids, and abundant enemata of cold water. Nothing should counteract this very urgent indication, so one can readily understand how advisable it is to be very chary in the use of intestinal antiseptics and sudorific drugs. One of the best intestinal antiseptics will be found to be calomel, which should be given in doses varying from one to two centigrammes every morning. The condition of the mouth and gums should be watched with care in case this drug is administered. The mouth is to be washed out frequently with a boracic acid solution or a one-per-cent chloral solution, rather than with a solution of chlorate of potash. Benzonaphthol as an intestinal antiseptic is much more innocuous than naphthol or saliol, and may be given in doses of two to four grains. As a means of producing perspiration, which is so often a symptom of amelioration, hot drinks, hot grogs, acetate of ammonia in doses of four to six grains a day, are much more useful than pilocarpine, which has such a deadly action upon the heart. It has been proven by Drs. Scherer and Quinquaud that toxic influences are brought about in many cases by the formation of incompletely oxidized products such as leucin, tyrosin, and similar chemical bodies. Their complete oxidation, either in the tissues or at the surface of the lung is urgently required, and inhalations of oxygen on the one hand, and on the other administration by the mouth of benzoate of sodium or of lithium, are the best means of increasing the oxidizing powers of the blood. These drugs are comparatively harmless, as they have no action on the kidneys. Benzoate of ammonia is useful when there is great dry-
ness of the skin. What has just been said applies with peculiar aptness to a special form of icterus gravis caused by phosphorus poisoning, and it is due to a certain extent to its oxygenating powers that turpentine has been so freely given in such cases. Capsules containing 0.25 centigramme may be given every two hours, the whole number daily being about ten or twelve. Dr. Carreau has given turpentine subcutaneously according to the following formula:

Ozonized turpentine, 10 grammes.
Liquid vaselin, 30 grammes.

These injections must be made with the usual antiseptic precautions.

Dr. Chauffard, physician of the Paris hospitals, has often found it useful in some cases of hyperthermia to give cold baths when the temperature of the patient is over 39° C. (102° F.). The results have been most gratifying. The cold bath should not be so rigorously applied as in typhoid fever, and the water is to be at 79°, 75°, or 71° F. The general reaction should be watched for with care. If the heart action is weak, caffeine or sparteine should be given, or even large injections of saline solution. Iced champagne is well tolerated. Hyperthermia is a worse symptom than hyperthermia, and should be treated by stimulation, alcohol, cutaneous rubbing, and injections of saline solution. When there is hemorrhage inhalations of oxygen are after all the best means of controlling the latter. Hydrastis canadensis in metorrhagia is often efficacious. Special indications are given by the causes of the disease. If this be phosphorus, turpentine is very useful, as well as washing out of the stomach to remove the phosphorus even twenty-four hours after ingestion of the poison; but no milk should be taken, nor any fatty foods, which serve to make the phosphorus soluble. When one finds on examining the patient that there is a past characterized by attacks of intermittent fever, quinine, which is not indicated in most cases, proves very beneficial.

In a recent review published by Dr. Babel, of Geneva, a certain number of new methods employed in Switzerland are indicated. Among the latter our readers may be glad to hear of a new mechanical device discovered by Dr. Treuthardt, of Cossionay (Vaud), designed to remove the mucous secretions that obstruct the trachea in some cases of infantile bronchial pneumonia. At an advanced period of this terrible malady one may notice that the child breathes with difficulty, and there is a tracheal sound which indicates that the bronchial tubes are filled with secretions. The patient seems by this time well-nigh gone, and it is at this period that Dr. Treuthardt seems to have been able to bring back to life a certain number of children of varying ages, even those of only two months old. The child should be placed horizontally in the arms of a nurse, face downwards; one hand of the nurse holds up the chest, another lifts up the head. The body is then energetically rubbed, especially the thorax, with woolen strips dipped in very hot wine, and between times sudden intermittent pressure is brought to bear on the ribs so as to keep up artificial respiration. Hiccough becomes more and more uncommon, and the mucous deposits can be removed from the mouth by inserting a finger covered with a cloth. This should be kept up until natural breathing has set in. Nausea should then be provoked by titillation, when small masses of mucous secretions will be removed, and the patient will recover from his condition of stupor. The child can then be put to bed and the frictions diminished in frequency, but the patient should not be left alone night or day, and especially he should be kept from falling asleep. Sleep in such cases means death, and the physician should use all his authority in such cases to have the treatment kept up and a cure assured. As soon as the patient can absorb food, light tonics are given him—for instance tea, either pure or with milk. When the child has become somewhat stronger and its bronchial tubes are sufficiently cleared, it may be allowed to sleep in the arms of its nurse, and should not be put to bed until one is sure that after half an hour's doze there is no tendency to suffocation. Convalescence sets in rapidly in such cases. The condition of the lungs should, however, be watched most carefully.

Dr. Lucas-Championnière, surgeon at the Hotel Dieu, who is well known for his having been one of the first to introduce antisepsis into France, recently read a paper at the Academy of Medicine on the treatment of hernias by the use of the bicycle. Dr. Lucas-Championnière cited Dr. Loir's works on this subject, which have been published recently. In the first case cited by the latter an inguinal hernia dating from four years back was recognized, and it was treated without success by compression. Cycling was recommended, but the seat being too high
the hernia kept on escaping under the bandage. In 1898 the patient took to riding a very low-wheel, and he found as a result that the hernia no longer escaped. Four months afterwards the patient was completely cured of his hernia. Exercise is excellent for patients suffering from hernia, and it is better that they should work too much than not enough. Dr. Jennings, of Paris, has shown by several observations published ten years ago that the use of the bicycle was capable of curing hernias. Dr. Mohamed, of Guy's Hospital, observed on himself personally the beneficial influence of exercise. Among elderly patients suffering from voluminous inoperable hernias the use of the bicycle has seemed to produce good results. As an explanation of this influence we can admit that the use of the bicycle suppresses the vertical position, and thereby the descent of the hernia under the influence of weight. The abdominal walls are also strengthened, as they are more frequently used. Moreover, obesity is to a certain extent removed and the hernia more easily reduced. A few practical hints should be given to patients in such cases; hills should be ascended on foot, and no scrathing indulged in. The bicycle must be chosen with a low seat and the saddle placed not over the tread, but much further back, as in this way the muscles of the abdominal wall are brought into play. Fencing and riding can be indulged in at a later date.

Dr. Lemoine, of Lille, professor of clinical medicine at the university of that town, has been trying methylene blue in some cases of acute articular rheumatism, and has found it in its action more efficacious and more rapid than sodium salicylate. It acts much better than salicylate of sodium in various forms due to gonorrhea. To be efficacious and harmless the drug should contain no zinc salts.

Professor Lannelongue, a friend of President Faure, who was called in to see him the day he died, spoke recently at the Academy of Sciences on the treatment of what he calls tuberculoses—i.e., tubercular abscesses. These, as is well known, may be isolated, or else due to some osseous lesion. As a general rule, these abscesses should be operated upon as soon as possible. Extirpation of the whole mass is undoubtedly the best operation that can be carried out, but this treatment can only be applied to a certain number of cases, where the lesion is quite limited. If the cavity of the abscess is large, opening up of the latter and curetteing are well indicated, and produce good results in some cases; in others the treatment by injections is successful. This treatment consists in tapping the abscess at a point where the skin is quite intact, removing the pus by aspiration, and washing out the cavity with a boracic acid or a carbolic acid solution. Once the liquid comes out perfectly clear, which indicates that the cavity has been thoroughly washed out, an injection is made of:

Sterilized almond oil, 90 grammes;
Iodoform, 10 grammes;
Ether, 10 grammes;
Cresote, 2 grammes.

Dr. Ménard, a former chef de clinique of Lannelongue, and surgeon-in-chief of the Hospital of Berck-sur-mer, which was founded for scrofulous children by the Empress Eugénie, generally uses a solution of naphthol and camphor, equal parts, which forms an oleaginous, dark-looking liquid. The results of this treatment are very satisfactory. In some cases one injection suffices; at other times several are found necessary. Dr. Ménard applies this treatment to all cases, and his results are most satisfactory. When the injection of camphorated naphthol, or, as it is called in French, "naphthol-camphré," is made, a small amount only should be left. So far as the writer of this letter can say, there never has happened any untoward effect arising from the use of this preparation, an affirmation that can hardly be made as to the iodoform injection, which to his knowledge was followed by death in one case. When alarming symptoms follow the injection, immediate evacuation and thorough washing out would be the only means of preventing the comatose condition and heavy perspiration from being followed by death.

President Faure's death has caused much comment amongst medical men, and it does not seem to be quite clear as yet whether it was due to hemorrhage or thrombosis, though the rapid progress and swift termination of the illness would seem to point to the former cause. There was what is called in France "paralysie alterne," so it must be admitted that the lesion was located in the pons Varoli or its neighborhood. President Faure had long been suffering from pronounced arteriosclerosis, and his consulting physician had counseled moderation in all physical exercises. The President was very fond of shooting and riding. However, the day of his death he had not been feeling well, and had given up his usual ride in the Bois de Boulogne.
ROME LETTER.

About two years ago a large and somewhat influential section of the Italian doctors started a crusade against all the foreign medical men who are permitted by the Italian Public Health Act to practice their profession among foreigners only in Italy. The object of this crusade was to induce the Italian Government to modify the above law in such a manner that the foreign doctors would be obliged to obtain a degree in one of the Italian universities before they were permitted to practice in Italy. They also wished that such modification in the law should be made retrospective—that is, that it should apply to the foreign doctors who were actually practicing in Italy. The reason assigned for this proposed change in the law by the Italian medical men was that all other countries obliged the foreign doctors, including the Italian, to obtain the diplomas of the respective countries before they could practice in them. The Italian doctors put their views before the Minister of the Interior of the Italian Government, and he gave them a favorable answer.

These facts having come to the knowledge of the British and American doctors practicing in Italy, they formed an association for the purpose of opposing the proposed change in the law. The association elected three of their members residing in Rome as a committee to look after their interests in reference to this question. The committee had an interview with the Under Secretary of State of the Italian Government, who was entrusted with the proposed modification of the law, and pointed out to him the injury that Italy would suffer in a financial way were the proposals of the Italian doctors legalized. It also stated that in England and in about half the States of America foreign doctors were allowed by law to practice their profession without obtaining the diplomas of these countries. The committee also brought the question before the General Medical Council in London, the various medical corporations in the United Kingdom, and the British and American ambassadors in Rome. The result of this action was that Lord Salisbury warmly took up the subject on behalf of the British doctors, and he induced the Italian Government to let the law remain as it was. This result was of course not satisfactory to the Italian doctors, and as soon as the new Italian Government came in they again appealed to it for the desired modification in the law.

A few weeks ago Dr. Santini, who is the champion of the crusade in the Italian Chamber of Deputies, begged the new ministry to bring in a bill to prevent foreign doctors practicing in Italy unless they possessed an Italian diploma. General Pelloux, the Minister of the Interior, declined to do so, but he promised that the Government would interest itself in a diplomatic way to obtain reciprocity of treatment in favor of the Italian medical men who practice their profession in other countries. The Italian ministry has quickly fulfilled the above promise, as the following circular has already been sent by the Italian Minister of Foreign Affairs to the Italian ambassadors in foreign countries:

Article 23 of the Italian law on Public Health, while it forbids, as a general rule, the practice of medicine in the Kingdom to those who are not possessed with the corresponding diploma acquired on the basis of our scholastic regulations, permits, by way of exception, that foreign practitioners may exercise their profession in Italy among foreigners only.

This exception, however, adopted in favor both of the foreign doctors and of the foreign residents in Italy, who may thus avail themselves of the services of the practitioners in whom they have confidence, is to the disadvantage of the native doctors through the competition thereby caused, and it is, in many cases, contrary to equity, inasmuch as the States are very few that, like Italy, accord an equal favor to foreign residents.

The Royal Government, therefore, has the intention of modifying the cited law in the sense of limiting the exception with which it deals in favor of those foreign doctors only in whose country our countrymen enjoy such special treatment.

I shall be thankful, therefore, if your Excellency will request from your Government an answer to these two questions:

1. Can Italian doctors there practice their profession among all or only among the foreign residents, without obtaining a new diploma?

2. In the negative case would your Government be disposed to accord to them such permission if in Italy we continue to consent to the doctors of this country practicing their profession within the limits above indicated?

It is to be hoped that England and America at least will respond favorably to this circular and agree to the adoption of reciprocity of practice with Italy, and thus put an end to the agitation.

In the Supplemento Al Policlinico of February 11, 1899, Professor Celli and Dr. Valenti, of Rome, published an important note on the "Etiology of Dysentery." The authors state that in 1896 Professor Celli published in extenso in the Annali d'Igiene Experimental his remarks on the "Etiology of Dysentery in its Relations with the Bacillus Coli and with
its Toxins," in which he demonstrated that the diagnosis of the bacteria can be made by the study of the action of their toxins, and by this means he differentiated from the many varieties of the B. coli that form which he called the bacterium coldysentericum, because he considered it the specific cause of dysentery in man. These researches were afterwards confirmed by Del Pino and by Alessandri. Since then the authors have continued their experimental observations on the toxic products of the same variety of bacteria, and in the respective antitoxinimmunity and antitoxitherapy. Using the toxin obtained from alcoholic precipitration of broth cultures filtered through blotting-paper, and reduced to powder toxiprotein—that is, a mixture of toxin and protein—after a long series of useless attempts of immunization of dogs they, on May 4, 1897, succeeded in immunizing an ass, at first subcutaneously and then endovenously. This animal after a long time no longer reacted to the toxic inoculations, so that they gradually arrived at from seven centigrammes of dry toxin injected subcutaneously to one gramme injected into the veins. The serum that they had obtained they call for brevity and clearness of explanation serum A.

Meanwhile Valenti studied the action of the proteins of the B. coldysentericum and, comparatively, of other B. coli, extracting them according to Koch's method for the new tuberculin. He demonstrated that they had no action in herbivora, and, instead, in dogs and cats a characteristic action, chiefly in the large intestine, and analogous to that of the above mentioned toxiprotein. With these two proteins, which they call C. O. and C. R., they tried to immunize two young asses. Of these two animals, that inoculated with C. O. died of very acute intoxication after the third injection and a dose of C. O. Cc. 18 = 38 milligrammes of dry substance. They, therefore, had to immunize with the same C. O. another young ass. They call serum B that obtained from the animal inoculated with C. R., and serum C that extracted from the animal injected with C. O. The three animals, inoculated respectively with dry toxiprotein, with C. R., and with C. O., are still undergoing the injection of the same toxic substances in the Milan Serum-therapic Institute.

The authors then give particulars of some of their experiments on kittens to demonstrate the degree of immunity reached and the value of the respective serums. The results obtained are that the serum A is the most efficacious both as a preventive and curative; the serums B and C act as preventives, but as curatives they have uncertain (serum B) or no action (serum C), succeeding only in retarding death for a few days. Death took place by marasmus, without any apparent organic lesions or intestinal localizations, which demonstrated that in the body of this B. coldysentericum, as in many other pathogenic and saprogenic bacteria, a marantic toxin is found, which, inoculated in animals, does not produce any counter-poison.

The authors note that the results of analogous experiments were not always equal to the preceding, and those in which they lessened the quantity of the serums were negative. So that for dysentery they were very far from those high degrees of active immunity and the consequent passive immunities that are obtained against distinctly toxic infections such as diphtheria and tetanus. With the best of their serums—that is, serum A—they experimented on the serum-diagnosis of several B. coli in the Bacteriological Laboratory of the Rome Institute of Hygiene. The results obtained with the hanging drop confirmed the specificity of the serum A in respect to the B. coldysentericum, and also confirmed the difference from the other bacteria of the same species.

During the last summer, an epidemic of dysentery being prevalent in Udine, the authors tried the serum-therapy. Having only a few cases at their disposal they wished to test the three serums, first inoculating subcutaneously serum A, and then the others. The results were as follows: Of six cases of acute dysentery, recently developed, with the serum treatment there was a rapid disappearance in all in two to five days of the sanguinolent feces, and ready cure; in a seventh case of twenty days' duration, in an old woman of eighty, also suffering from mitral insufficiency and parenchymatous nephritis, the serum-therapy had no action. At the same time, of four other patients who were admitted into the hospital suffering from acute recent dysentery and treated in the ordinary way, three died. The authors state that these results have encouraged them to continue the immunization of their animals to prepare the serum for testing on a larger scale.

Recently Shiga, of Kitasato's Institute for Infectious Diseases, has published a work in which he confirms the fact that the cause of dysentery is a variety of the B. coli, which he
has differentiated by means of serum-diagnosis—that is, with the serum of the blood of persons suffering from dysentery. To solve the doubt that Shiga has raised as to the identity of his bacillus dysentericus with the bacterium dysentericum (Celli), the authors retested and compared its cultural characters, and they found that after many successive passages through animals and in cultures for preserving or exalting the virulence it maintains itself a typosimile, as is the B. dysentericus. The authors then describe the appearances in gelatin stab cultures, and the results of the serum-diagnosis with the serum of the blood of dysenterics, and they have come to the conclusion that, according to every probability, the bacterium colidysentericum (Celli) is identical with the bacillus dysentericus (Shiga).

Professor De Dominicis has published an article in the Gessetta degli Ospedali e delle Cliniche on the influence of fasting in the treatment of acute infectious diseases, in which he says that an inexact valuation of the advantage of feeding patients, through a misunderstanding or an inopportune desire to sustain the forces, frequently turns out injuriously. The observations made at the bedside for more than twenty years have convinced the writer that the disturbances of digestion, producing perhaps on the one hand insufficient reparation, and on the other a reproduction of toxic substances, generate maladies of diverse kinds. These views are supported by the observations of able clinicians, who have given solid support to the doctrine of dyspeptic auto-intoxications, in which he was one of the first, if not the first, to call attention, especially when Bacellii, apropos of the discovery of the infective agents, had foreseen the bacterial toxins. Owing to the light which bacteriology has thrown on the etiology of diseases, De Dominicis has convinced himself that these alterations in nutrition give a substratum or a reinforcement to the virulence of diseases. The experiments of the laboratory had confirmed these views. In not a few extirpations of the pancreas, performed in dogs and other animals, the author observed that the animals who had eaten before the operation, or soon after, generally died, whereas those who were kept fasting for one day before and two days after the operation nearly all survived. In a series of starved dogs treated with active cultures, or with their toxic extracts, or by diverse traumatisms, the pathological changes were not as marked as in those which were met with in dogs kept on ordinary diet. Several other experiments have demonstrated to him that fasting, within certain limits, renders animals, as well as men, more resistant to microbic actions. Tissier and Guinaud had similar results in animals intoxicated with toxins of the pneumobacillus and of the diphtheria bacillus.

Finally, the author referred to a man of thirty-five years affected with influenza, and treated with abundant alimentation, who became very dangerously ill, and through intense headache, vomiting, giddiness, titubation, etc., followed by delirium and coma, was thought to be suffering from a tumor of the cerebellum. The author advised keeping him fasting until the awakening of his digestive capacity, and also free lavage of the stomach. After four days of this treatment the patient regained consciousness, and gradually recovered.

A ZINC COLLODION CAUTERANT PASTE FOR EPITHELIOMA.

To the Editor of the Therapeutic Gazette.

Dear Sir: A gentleman about sixty years of age recently presented himself for the removal of an epithelioma involving the skin and subcutaneous tissues, and situated in the nasal corner of the eye. The growth was about three-quarters of an inch in diameter and typically epitheliomatus in appearance. It seemed especially well suited for treatment by cautery.

Wishing to apply the escharotic in such wise that the patient should not be compelled to wear bandages, and so that the irritating application should not gain access to the eye, I combined the adhesive properties of colloid with the destructive ones of zinc chloride, taking equal quantities of each ingredient. With this paste the growth was painted, the application being renewed every second day. Before each renewed application the coating was removed with ether, after which fomentations with hot water separated the necrotic tissues from the living.

By this means the entire growth was removed, after which the granulating tissue was protected by a layer of boric acid ointment, until complete cicatrization was accomplished; this latter process being hastened by a five-per-cent solution of silver nitrate.

The cosmetic result was extremely favorable, no trace whatever being left of the malignant neoplasm.

The Pharmacopoeial Convention of 1900. 359

Further attempts to formulate our present knowledge, and I have therefore thought that it might be of interest to discuss some of the still unsettled points with regard to the varieties and treatment of the disease in the light of some of the recent writings. The older classification of Hebra, which one might almost call the first definite one, was into idiopathic eczema, or that caused by local irritants and injuries, and symptomatic, or that resulting from internal causes. This was of course an etiological classification, but there were at that time, and remain to-day, slight enough grounds for this division, since little was known about the external agencies producing the disease and practically nothing

*Read before the Harvard Society, Feb. 16, 1899.
about the internal ones. Another classification which rested less on pure theorizing was that into acute and chronic, but here the words were used apart from their general meaning in medicine, referring more to the intensity of the process than to the rapidity of its course. Many other subdivisions were also made, but these mostly referred either to stages in the process, as eczema rubrum, eczema squamosum, or to regional distribution, as eczema palmar, eczema faciei, etc.

In 1887 Unna collected all the symptoms which the various authors had previously grouped under the heading of seborrhoea, together with some forms of eczema and psoriasis, and designated the class so formed "eczema seborrhoeicum." This class has, I think, with certain reservations been almost universally accepted.

We have, then, if we are going to agree with the innovation introduced by Unna, two varieties of eczema, one of which we may call simple and the other seborrhoeic, and with your permission I will proceed to examine the evidence upon which this second variety is based. Unna found on examination that attacks of eczema of the head, body, and limbs were often preceded by a scurfy condition of the scalp. This scurfy condition is what was previously known as pityriasis capillitii. He also noticed that in many of these cases one could find on close examination that as well as the patches of eczema there were also often present typical patches of what was previously known as seborrhoea corporis or lichen circumscriptus. He then examined these two conditions histologically—namely, pityriasis of the scalp and seborrhoea corporis—and found present changes which he considered to be characteristic of eczema, these being an incomplete production of keratin, associated with proliferation of the epithelial cells, and an edematous condition of the deeper layers of the epidermis. Now if we stop to consider these changes for a moment we shall, I think, see that they are the changes which are always associated with inflammation, namely, loss, or partial loss, of function, increased cell production, and increased lymph exudation. It would therefore appear that it is unjustifiable to assume that these changes are characteristic of eczema; in fact, we find much the same in psoriasis, and this fact it was, I believe, which led Unna to state that psoriasis was nothing but a variety of seborrhoeic eczema. But in the mildest form of the chronic scurfiness of the scalp the cell proliferation may be very slight or absent, and the edema of the deeper epithelium very trifling, so that it seems hardly justifiable to rank the condition as an inflammation at all.

Psoriasis was included by Unna under the heading of seborrhoeic eczema because in the first place he found the changes in the epidermis already referred to as present in pityriasis of the scalp, and also because he found present in the scales the morococcus, which he considered the pathogenic microbe of eczema. In classing psoriasis with eczema he met with great opposition from nearly all other authorities, since the disease, although sometimes difficult to distinguish from cases of seborrhoeic eczema, has so many characteristics of its own that it is almost impossible not to regard it as a clinical entity. On the other hand, it is no reason for disputing its independent existence that it is occasionally closely simulated by another disease, as we know how difficult it may sometimes be to distinguish syphilis from psoriasis, although we feel certain that there is no relation between the two.

If, then, we are to exclude both cases of psoriasis and simple pityriasis of the head from the category of seborrhoeic eczema, does anything remain? I think there does. There are certainly many cases of what we cannot call simple seborrhoea of the head, body, or extremities, which yet appear to have supervened upon the simple seborrhoeic states, and which may therefore be justly called seborrhoeic eczema. Such an eczema generally, but not invariably, starts on the scalp and works its way downwards, taking the central grooves of the chest and back as its path, and usually not affecting the limbs until later. This variety of eczema deserves, I think, separate notice, from the reason that it has several important characteristics of its own. In the first place, it nearly always appears to begin in the follicles, though later it may spread to parts such as the palms and soles, which possess no follicles; secondly, it is nearly always sharply defined at the margins of the patches; thirdly, it tends to spread serpiginously. In Unna's original description of the disease these characteristics are thoroughly brought out with the exception that, in my opinion, he did not lay sufficient stress on the affection of the follicles as distinguishing this from other forms of eczema. There are, of course, other points of interest about this variety, such as the greasy nature of the scales present and the usually small amount of serous discharge found even in moderately
acute cases. These latter are, however, not sufficiently constant to be considered diagnostic of the disease. It still remains an open question whether this disease, when acutely inflammatory, is to be considered an eczema or not, several well known authorities preferring to call the disease seborrheic dermatitis, since they believe that it may be distinguished from true eczema. Audry published a case of great interest in the Annales de Dermatologie for 1897, page 551, in which the disease attacked a waiter who had been severely burned in early life, so that the outer surface of the left arm was occupied in its entirety by a large, deep cicatrix. The patient gave a history that the disease began with a red patch on the left cubital region, which soon discharged and then crusted over. The point of interest in the case lay in the fact that when seen the disease had spread so as to encroach on the area of the cicatrix for over half an inch, and in addition to this there were two independent patches lying in the very center of the scar. On the back of the right arm there was a large patch, which Audry describes as being as typical as possible of seborrheic eczema. While in the hospital two inoculations were made from the diseased area, one being into healthy normal skin, the other into the healthy scar tissue. Three days later the point of inoculation into the normal skin showed a typical patch beginning, while the inoculation into the scar tissue remained without effect. From this case Audry concludes that the disease called seborrheic eczema is autoinoculable on its subject; that it may develop on a scar which is completely deprived of the elements furnishing the fat, and this is a characteristic which it shares with psoriasis; that it develops better on normal skin. I have quoted this case for two reasons: first, that it points strongly to the fact that seborrheic eczema is a parasitic affection, and secondly, that it proves that the disease may develop on parts of the skin which have neither sebaceous nor sweat glands.

Apart from this almost universally acknowledged form of eczema, there are one or two other varieties which have been described and deserve some notice. First there is the form described by Morris under the name of eczema folliculorum, and on which he read a paper before this Society just ten years ago. Following his description I am unable to distinguish it from a very chronic form of deep seated seborrheic eczema, but I have not had the opportunity of seeing a case, and he informs me that it is a very rare disease. Morris himself is convinced that it is a clinical entity, and seborrheic eczema is so common a disease that the two are not likely to be identical, although possibly allied, eczema folliculorum being a connecting link between eczema and syecosis, to the latter of which Morris himself believes it to be related. Neisser has described some cases of what he calls eczema folliculorum after Morris, but I think that his disease is undoubtedly our old friend seborrheic eczema. The disease begins in the follicles, especially on the back, but affects other parts as well, and then usually runs into patches. I am perfectly familiar with the disease described by Neisser and illustrated by him by photographs. The rash begins as red, hard papules scattered widely over the back, each papule corresponding to an enlarged and prominent follicle. Usually, but not invariably, the original papule flattens down and the disease spreads centrifugally, picking out the follicles as it goes. The intervening skin is reddened and may be scaly. In some cases the disease shows very little tendency to this serpiginous advance, and new follicles are affected at a distance instead, probably by infection from scratching or the rubbing of the clothes. Neisser thinks that the accompanying eczema is probably independent, but I think it is much more likely to be a part of the same process. Probably the parasite, whatever it be, grows much more easily in the follicles than on the surface epithelium; and Neisser's contention that the eczema may be cleared off while the follicles remain affected seems to me to find an analogy in the manner in which one may clear off the ringworm fungus from the surface of the skin but find it difficult to eradicate from the follicles.

Next there is the disease described by Hans Hebra as eczema mycoticum. This is an extremely obstinate affection of the follicles, accompanied by some serous discharge and a considerable crustling. It is seated chiefly on the flexor surfaces of the joints, and is especially apt to attack the scrotum and the anal fold. It is accompanied by such furious itching that the patient's life becomes a burden to him. In appearance the disease is characterized by a good deal of thickening and crustling of the skin, while the follicles are picked out as very hard and rather pale papules. While I was attending Hebra's clinic he was treating all his cases with strong applications of chrysarobin in traumaticin, and with great success, so that as he found
organisms present in some cases, it is almost
certain that the disease is parasitic.
Lastly, Crocker has described a form of
eczema which he calls eczema circumscript-
tum and believes to be parasitic. This dis-
ease occurs in patches of red papules below
the knee, but his description does not say
whether the follicles are much affected or
not. It appears to be somewhat easily cured
by a weak parasiticide ointment.

These diseases all bear a strong family
likeness to each other and to seborrhic
eczema, though they are probably not all
cased by the same parasite. Until, there-
fore, the various parasites are discovered and
we are able to class them definitely, as we are
some of the forms of ringworm, I think it is
simpler to group all these cases under the
heading of seborrhic eczema.

Leaving the question of seborrhic eczema,
we return to the so-called simple eczema.
Of the etiology of this disease we are almost
entirely ignorant, and as it would take much
too long to enter into the various theories
held with regard to its causation and pathol-
ogy I shall content myself with referring to a
few points of practical importance. There
have for a long time been two main opinions
on eczema, one that it is the outward mani-
nestation of some inward disorder—that is,
that it is a constitutional disease—and the
other that it is an entirely local disorder due
in the action of some local irritant, parasitic
or otherwise.

Leaving out all such obscure theories as
the dartrous diathesis of Hardy, there re-
mains one definite disease which has been
believed to stand in causal relation to eczema
by many good observers. It may be of inter-
est to glance at the facts that are known
about this relationship. At the Congress
for Internal Medicine in 1891 Garrod read
a paper emphasizing the frequent association
of gout with eczema. His chief points were
as follows: Patients who have suffered from
acute articular gout are specially liable to at-
tacks of acute or chronic eczema. In such
patients the disease has been especially no-
ticed to occur in dry springs with a cold east
wind, and in such cases it has also been no-
ticed that the regular spring attack of articu-
lar gout has not occurred, which looks as if
the attack of eczema had replaced the gout.
Women of gouty family history are liable to
attacks of eczema about the climacteric, at-
tacks of true gout being delayed until after
the cessation of the menstrual flow. Lastly,
Garrod mentions the case of a gouty patient
with eczema who found that the ingestion of
urate of soda caused a great irritation of the
eczematous patch, this irritation quickly sub-
siding on discontinuing the drug.

As regards the form and distribution of
this so-called gouty eczema, it may be either
acute or chronic, and it affects, in order of
frequency, the external surfaces of the ears,
the meatus and the skin behind the ears, the
back of the neck, the eyelids and different
parts of the face, the groins and other in-
ternal surfaces of the flexures of joints, the
scrotum, glans penis, and prepuce. Further,
it may affect the hands and feet, especially
the dorsal surfaces of the fingers and toes,
and it may attack the arms and legs and be
scattered all over the body. From this we
see clearly, I think, that there is no special
characteristic which will serve to tell us
whether any given eczema is gouty in
origin or not.

As regards treatment Garrod says that the
acute attacks, especially when replacing an
attack of articular gout, are easy to cure with
the ordinary treatment for gout, but that the
chronic forms are often very resistant. This
corresponds to our usual experience of the
disease, namely, that acute attacks recover
almost by themselves, whereas chronic patches
often defy treatment. I think from this we
may conclude that there is a special prone-
ness to eczema in gouty patients, but that we
are not justified in inferring the presence of
gout from the presence of eczema, an infer-
cence which I am afraid is often drawn. We
are perfectly well aware that gouty patients
are especially liable to attacks of acute bron-
chitis, but we do not infer on seeing a patient
with bronchitis that there is of necessity a
gouty tendency at the bottom of the attack.

Garrod has pointed out in the paper from
which I have just quoted that in these cases
of gouty eczema one cannot easily demon-
strate the uric acid by the thread test, and
explains this by saying that uric acid is de-
stroyed in parts which are undergoing acute
inflammatory processes. It seems, therefore,
easy to understand that a wide-spread weep-
ing eczema will naturally destroy so much of
the uric acid in the blood that an attack of
articular gout will be averted. Hence it
would seem possible that the sudden drying
up of an acute eczema in a gouty patient
might be followed by an acute attack of gout,
but that this should occur in the chronic
forms would be in the highest degree un-
likely. In this connection the researches of
Colombini are of considerable interest. This
observer investigated the varying degrees of toxicity of the urine of healthy and diseased human beings when it was injected into rabbits. His results were as follows: In acute weeping eczema the toxicity is decreased, returning to normal in most cases when the eczema is cured. In chronic dry eczema the toxicity of the urine is increased, again returning to normal with improvement in the disease.

Now I think the explanation which would naturally suggest itself of these facts elicited by Colombini would be that the changes in the toxicity of the urine depend upon the state of the skin, and not that the state of the skin depends upon that of the blood as reflected in the urine. In the case of the weeping eczema a large amount of secretion is taking place from the cutaneous surface, and this naturally leaves less to be done by the kidneys; with the cessation of the discharge from the skin the kidneys have to do the whole of the work previously partly done by the skin, hence the rise of the toxicity to the normal degree. In the case of the chronic dry eczema the normal cutaneous secretion is diminished or suppressed, and hence the kidneys have to do more than their usual share of the excretory work of the body and the toxicity of the urine rises above the normal, while with the return of the cutaneous secretion the toxicity of the urine is diminished, resuming its proper degree. So that as far as it goes the work of Colombini appears rather to militate against the supposition of a toxemia as the cause of acute eczema, since were this the case one would expect to find the kidneys excreting at least as great an amount of toxic substance as normal, whereas, as we have seen, the amount undergoes a diminution.

From these results of the examination of the urine in acute eczema it would seem that if it were possible to suddenly and forcibly dry up the discharge in a patient whose kidneys were not sufficiently sound to respond to the call for a sudden increase of work, the results might be dangerous from the accumulation of toxic substances in the blood. In the case of the dry eczema it is obvious that there can be no danger in clearing the skin of the disease as rapidly as possible. Returning to the first case for a moment one would naturally wonder that with the frequency of acute eczema one does not more often see the results of this sudden suppression of the discharge than is the case. The explanation of this lies, I think, in two circumstances. The first is that in most cases of acute eczema the kidneys are fully able to excrete the normal amount of deleterious substances, which is all they are required to do; and the second is that in cases where the kidneys are not able to perform their work we find it impossible to suddenly suppress the discharge. Nevertheless, cases have been published by Brocq, Brooke, and others which tend to show that the attempts at curing a weeping rash have sometimes been followed by untoward results.

Brooke's case is so much more convincing than any of the others that I have read that I should like to refer to it here. The patient was a child suffering from an acute eczema of the head, which was treated with small doses of Fowler's solution and zinc ointment. The head got well, but the recovery of the skin was at once followed by a severe attack of bronchial catarrh. The scalp was then poulticed and the eczema reestablished, and the child recovered. The parents, however, were so anxious to have the child's head relieved of the unsightly rash that treatment was resorted to a second time, whereupon the bronchitis reappeared and the child died of what might be called metastatic edema. These cases are, however, of such rarity that one would feel almost inclined to disregard the danger from that reason alone.

But this is not the only argument in favor of treating all cases of skin disease. Bernheim in 1894 described the case of a child with a wide spread eczema accompanied by large pustules who died suddenly in hospital. A bacteriological post-mortem was made and revealed the presence of staphylococcus pyogenes albus and vitreus in the liver, staphylococcus albus in the heart, and both staphylococci and the diplococcus albenis tardus in the brain and pericardium. Here we have, I think, a much more serious danger, namely, the risk of septic absorption or septic infection from large areas of skin denuded of its protective horny layer, and in my opinion the occurrence of one definite case of this kind is an argument for the rational treatment of all skin diseases far outweighing that for leaving them alone, based upon the supposed metastases already referred to.

The reference to this case of Bernheim's brings me to the second theory of the causation of eczema, namely, that it is a parasitic affection. Unna was, of course, the great upholder of this theory, and considered that he had found the pathogenic microbe in the so-called morococcus. He further considered
that seborrhoeic eczema was due to the same organism complicated by the presence of some other factor, possibly another organism. This opinion did not, I think, gain very many adherents in this country, as the balance of evidence seemed to be against it, and moreover it involved the merging of psoriasis into eczema, an arrangement to which I have already stated English authorities were unwilling to subscribe. In 1898, however, Leredde, of Paris, published a monograph on eczema in which he asserted with the utmost positiveness that eczema was a parasitic disease, and certainly defended his position very ably by what he termed histological, bacteriological, and clinical proofs. This work was, however, not to pass unchallenged, and a criticism of it has recently appeared in the December number of the Annales de Dermatologie, by Török, a former assistant of Unna’s, and therefore one who would naturally be very familiar with his teachings. Török points out that the histological proof of Leredde falls to the ground immediately because of the fact that Unna himself expressly states that there are two varieties of vesicle in eczema, in one of which the morococcus is found abundantly, and in the other sparsely or not at all, and that any one reading Unna’s description of these two varieties will at once see that the vesicle which corresponds closely to the lesion always regarded as the typical eczema vesicle is that in which the morococci are not abundantly found. For the same reason the bacteriological proof is wanting, because Unna took for his vesicle one which was clinically indistinguishable from an impetigo lesion. After carefully considering the question and reading both sides, I have come to the conclusion that much of the argument is based on the wrong use of terms. There seem to me to be at least two diseases, one of which we may call simple eczema, the cause of which is entirely unknown, and in which there is no shadow of proof of a parasitic origin, the other being the so-called seborrhoeic eczema, in which there is strong presumptive evidence that there is a parasitic agency, though at present an unknown one, at work. That the former may supervene on the latter is very probable, as we sometimes see undoubted eczema start on the head and attack the whole body, in cases of tinea tonsurans where the treatment with irritating drugs has been overactive. Whether the infective form deserves the name of eczema or not is a point into which I cannot enter here, but I think the name is now sanctioned by usage, and I have therefore applied it to the disease described by Unna rather than further complicate the already unwieldy nomenclature of dermatology by the introduction of new names.

Now the natural object of all medical inquiry and research should be the establishment of improvement in treatment, and it may therefore be asked, What value has all this discussion from the point of view of the patient? I think it has a very distinct value. If we can be certain in any given case of eczema that we have to deal with an attack of seborrhoeic origin and therefore as I believe of infective nature, we may at once try the effect of antiparasitic remedies, and therein lies the great advantage of an accurate diagnosis. In a seborrhoeic case, even when the process looks rather acutely inflammatory, one can often boldly resort to antiseptic treatment from the beginning with great success. If there is very great weeping one may use some mildly antiseptic lotion at first until the acute stage has passed off, such for instance as a one-per-cent solution of resorcin, and then, as soon as the discharge shows signs of ceasing, stronger applications, generally in the form of ointments or pastes, are to be applied. The drugs which I regard as most valuable in this variety are sulphur, salicylic acid, and resorcin in the order mentioned, and they can be combined if necessary in an ointment containing from ten to thirty grains of each to the ounce of base. By following these lines of treatment it will be generally found that the rash dies away with surprising rapidity. But here a word of warning is necessary. If, as is very commonly the case, the disease has spread from the scalp downwards in the classical manner, it will be found that although the scalp rapidly clears of all scaling during the actual application of the ointments, the disease begins to crop up again the moment the treatment is suspended. It is therefore advisable to continue treating the scalp long after all symptoms of the disease have disappeared.

In the treatment of what is known as simple eczema, if we consider that there is at present no proof of a parasitic origin, we shall be naturally less anxious to apply active antiparasitic treatment. It should be enough, and usually is so, to use some application which is not at all or very slightly irritating, and yet has an inhibitory action on the growth of any ordinary cocci which will be sure to gain access to the skin, denuded as it
is of its protective horny layer. There are many such lotions, and it is unnecessary to enumerate them, but mention may be made of a somewhat recent innovation, namely, a half-per-cent solution of picric acid in water. This lotion was originally introduced as an application for burns of the second degree, but has also been applied to acute weeping eczema. I have tried it in one or two cases, and I must say that I have not found it nearly so efficacious in weeping eczema as I have in cases of burns. Pastes are much favored for this stage of acute eczema by many authorities, but I am not very fond of them where the serous discharge is abundant, as they tend to form a cake on the surface and thus prevent free drainage, which seems to me to be the all-important point in the treatment of the acutely discharging diseases. Later, when the weeping has ceased, one may content oneself with simply protecting the surface with some ointment, and in this stage I do not think the composition of the ointment is of so much importance as the consistency, provided that it contains no irritating ingredients. It is advisable to use an ointment of good "body," as otherwise it soon runs with the heat of the part and soaks into the covering, leaving the skin practically dry. For this reason the unguentum paraffini of the Pharmacopoeia, or Hebra's unguentum diachyli, is very suitable, while vaselin is almost useless. As soon as the inflammatory redness has disappeared, one may attempt to restore the normal condition of the skin by mildly stimulating ointments, of which a weak tar ointment is perhaps the best.

In spite of the best treatment, however, one will sometimes find that there remains a considerable thickening of the skin due to cellular infiltration of the corium, especially if there have been repeated attacks. In this case, where there remains a chronic patch of thickened skin which resists ordinary treatment, Jacquet has advised scarifying the surface and bathing with warm water afterwards to encourage the bleeding. In this method of treatment the surface must have been previously cleaned by the application of starch poultices. I have no experience of this treatment, but have usually seen these patches yield either to the old soft-soap treatment of Hebra, which I think has been unduly slighted of late years, or the constant application of salicylic acid plasters.

In resistant cases of eczema of the palms and soles the main indication is to remove the thickened horny layer, so that the drug may come into contact with living epithelium below. Jamieson has had great success lately with Unna's oxidized pyrogallic acid in such cases. He first removes the horny layer by constant starch poultices for a day or two, the surface being briskly rubbed with a rough soft towel between the different changes of poultice, and then the ointment containing the drug in a strength of one to six per cent is applied thinly to the part and bound on.

It is, of course, impossible in a paper like this to go thoroughly into the details of the treatment of such a protean disease as eczema, and I have therefore contented myself with merely referring to some of the more recent additions to our methods. The great desideratum is the knowledge of the causation of the various types, as I am convinced that in the parasitic forms one may use strong antiseptics much more boldly than in the so called simple variety.

---

**ON THE USE OF THE TINCTURE OF CANTHARIDES IN CHRONIC PARENCHYMATOUS NEPHRITIS.**

**BY JULIUS SALINGER, M.D.,**
Chief of the Medical Clinic of the Jefferson Medical College Hospital.

Among the diuretics that are of use in chronic renal disease, especially in the form known as parenchymatous nephritis, that have fallen into disuse, or at least into insufficient use, is the tincture of cantharides. Only in a few of our modern text-books is it recommended as a reliable remedy, having distinctive powers, especially as a diuretic. From a very large experience in renal cases, especially in the Philadelphia Hospital, where, probably, the severest forms of kidney disease are met with, the writer has come to the conclusion that not only is cantharides a valuable diuretic, but that it has also distinct curative powers. Its chief use consists in its diuretic action, when employed in small doses, so as not to produce irritating effects. A few illustrative cases selected from a large number will readily prove this assertion.

Charles Williams, aged fifty-three, white, a laborer by occupation, was admitted to the Philadelphia Hospital July 7, 1895. His family history does not contain anything that bears upon his present illness. He denied venereal disease, but admitted having used...
alcohol to excess for the last ten or twelve years.

On Christmas night, 1894, the patient was on a debauch, when he exposed himself by lying out in the cold and wet, and was admitted to this hospital suffering from all the symptoms of acute nephritis. He was discharged April 27, 1895, feeling perfectly well.

One week before the present admission to the hospital, while intoxicated, he was exposed to rain and became very much chilled. His body, especially the lower extremities, began to swell, and he was in a critical condition when he was admitted to the ward. His breathing was rapid and labored, his legs and feet were enormously swollen, and the anasarca was so great that there was pitting all over the body upon the slightest pressure. The second aortic sound was greatly accentuated, and the lungs were filled with coarse moist râles. The pulse was full and bounding. The skin, especially of the face, had the peculiar yellow, waxy appearance so common to renal disease.

On admission patient was passing eleven ounces of urine in twenty-four hours. The specific gravity was 1020, color reddish, no sugar, albumin one-third by bulk. Upon microscopic examination wide and narrow hyaline and granular casts were found in abundance. The patient was extremely restless and dyspneic; in fact, he was so short of breath that it was impossible for him to remain in a recumbent position in bed. He seemed to grow worse hourly. He was unable to sleep, and furthermore was troubled by a racking cough. His nervous symptoms steadily grew worse. Delirium soon set in. He would talk to himself, and on one occasion, not being carefully watched, was found wandering about in the ward. He could no longer answer questions intelligently. Morphin, trional, chloral, and bromides were used in addition to the usual depleting remedies in order to induce sleep, but of no avail. He was given hot-air baths, his chest was dry-cupped anteriorly and posteriorly, and salines were freely administered.

Having had some experience with the tincture of cantharides as a diuretic, I ordered the following prescription:

Liquor ferri et ammonii acetatis, f 3 sa;
Tinctura cantharid., n 1j.

Given every four hours.

The kidneys promptly responded to these measures, but the dyspnea and uremic phenomena were not much relieved. Twitching of the face and convulsive movements of the muscles of the hands and fingers were noticed, particularly while the patient was delirious.

On the morning of July 7 (six days after admission) patient was very delirious; he was gasping for breath, and his face was fairly purple. His pulse was full and strong, showing high tension. It was decided to at once resort to venesection. Fifty ounces of blood was taken from the arm. Before the blood-letting was over the breathing became less labored, his mind cleared up, and he remarked, "I am feeling easier." From that time on his nervous symptoms disappeared, and he gradually though steadily improved. The same treatment was continued, the diet consisting absolutely of milk.

Three weeks after admission the edema had all disappeared. The patient felt perfectly well, although still a little weak. On July 28, 1895, he was up and about the ward. There was no cough, no dyspnea, the breathing was normal, the râles had all disappeared. The heart sounds were normal; there were no symptoms, except a slight irritability of the stomach. The albumin was reduced to the merest trace. No tube casts were found on repeated examinations. He was passing an average of seventy ounces of urine in twenty-four hours. His temperature throughout the attack had been subnormal.

August 1, 1895, Dr. de Schweinitz reported the eye ground as negative. On August 13 patient was discharged from hospital in good physical condition. The following is a daily record of his urine:

Another case even more striking is the following:

James Heffem, aged thirty-nine, white, born in Ireland, unmarried, driver by occupation, was admitted on June 25, 1895. His family history gave no evidence of hereditary disease. Until two and a half years ago he had always enjoyed perfect health. He had been

* Administration of tincture of cantharides begun.
† Venesection.
‡ Large number of stools, and urine lost with feces.
§ Urine lost with stools.
a habitual user of beer and whiskey, and used tobacco freely. He denied specific history. In December, 1892, while at work driving a team, he noticed that his feet, and later his legs, began to swell. He also became short of breath, which incapacitated him for work, and he was admitted to the Philadelphia Hospital, where he remained for eight weeks. He was discharged much improved. Since then he has been in the institution three times with the same trouble. He came the last time on January 25, 1895, suffering from marked dyspnea, which became extreme on the slightest exertion. His heart was so weak that the apex beat was not visible, nor could the heart sounds be heard. Percussion showed the cardiac dulness to be much increased, and other physical signs showed the presence of hydropericardium. His lungs were full of moist râles, except at the base, where there was evidence of hydrothorax. On account of the dyspnea he was unable to sleep except for a few moments at a time. His feet and legs were greatly swollen, and his serous cavities showed evidences of effusion.

On admission patient was passing from ten to thirteen ounces of urine in twenty-four hours, specific gravity varying from 1010 to 1030, albumin one-eighth by bulk, and hyaline and granular casts were found in great abundance. His temperature was 97°, pulse 120, respiration 40, and throughout the whole course of his disease his temperature was slightly subnormal. On admission he was more or less delirious; he muttered and talked to himself or to unknown persons. Three days after admission he had a uremic convulsion, for which he was given a steam bath for one hour. During the bath he perspired profusely. His nervous symptoms were relieved, his kidneys resumed action, and he entered upon a rapid and uninterrupted recovery.

Patient’s diet consisted of milk alone. He was given the following prescription:

Tinct. cantharid., m. ij;
Liquor ferrif. et ammonii acetatis, f. 1 ss.

Given every four hours.

The dropsical symptoms were speedily relieved, and in one week’s time he was passing 125 ounces of urine daily.

On July 25, 1895, the dropsy had all disappeared. He had been up and about the ward for three weeks and was feeling comparatively well. His urine was normal, and no albumin could be found in it by either nitric acid or heat test. His heart was still weak, but the sounds could be heard distinctly. There were no murmurs. The respiration was normal; there was no cough or dyspnea. The following is a record of the urine:

Many more cases could be quoted, showing similar good results. The cases are given in detail because the symptoms were urgent, and the results obtained so beneficial. In the writer’s opinion the tincture of cantharides administered in small doses (so as not to prove an irritant to the kidney) holds one of the chief places as a diuretic in renal diseases. Care, of course, must be used in giving the remedy in small doses, as overdose readily prove irritating to the renal substance. Senator, in Nothnagel’s “Spezielle Pathologie und Therapie,” vol. xix (Die Erkrankungen der Nieren), page 64, says Bayer and some of the older authors specially recommended tincture of cantharides, but he does not advise it, as in his experience, after other diuretics had failed, he had never seen any benefit from it.

This is, of course, entirely at variance with the cases just cited, and altogether different from the results obtained by me in the treatment of a large number of specially severe cases of chronic parenchymatous nephritis.

THE CARE OF THE TEETH DURING SICKNESS, AND THE PHILOSOPHY OF LANCING CHILDREN’S GUMS, FROM THE STANDPOINT OF THE DENTAL PRACTITIONER.

By JOSEPH HEAD, M.D., D.D.S.

It seems to be the province of a dentist, in addressing a medical body, to call the attention of the fraternity to the injury that is constantly being inflicted on teeth by the careless administration of drugs. This arises from the fact that the teeth do not rank as vital organs, and therefore no dentist, how——

*Administration of tincture of cantharides was begun.
devoted to their preservation, would say that cases might not arise in which they should be sacrificed to the welfare of the general system. For instance, in syphilis and other conditions of equal importance no one can doubt that mercury, given to the point of salivation, is sometimes essential; but the dentist is frequently brought face to face with the proofs that teeth have been sacrificed when no such necessity existed.

It seems to me that in the administration of acid medicines carelessness prevails, and when precautions are taken, in most cases they are ineffectual. By precautions I allude to the use of the glass tube, or the mixing of the acids with syrups, glycerin, or other bland fluids. The glass tube is ineffectual because some of the acid invariably creeps around the root of the tongue, and rests in the floor of the mouth; and the syrups and glycerin, though seemingly palliative, really only modify the action of the acids through their viscosity.

The only sure method of obviating danger to the teeth from the use of acids is by means of alkaline washes held in the mouth after the acid has been swallowed, and it should be swallowed as rapidly as possible. This absolutely prevents injury, as the acid is thereby neutralized before it has penetrated the mucous coating of the teeth. A solution of bicarbonate of soda is most efficient.

It is quite frequently the case that teeth have been not only roughened, thus making them accessible to the germs of decay, but riddled with cavities by the administration of acids during transient illness. Decay always starts with an acid dissolution and roughening of the tooth surface, whether this acid comes from fermentation of carbohydrates, colonies of bacteria, natural secretions, or medicine. In fact, tooth structure is so wonderful and beautiful a substance that nothing can start its dissolution excepting mechanical injury or acids.

A dentist who has guarded the mouth of a child from infancy, prevented crowding, strengthened weak places, taught habits of care, has a right to hope that the child at the age of fifteen will suffer little in the future from its teeth, and when after a temporary illness the same child is brought to him with the teeth so injured by medicine as to cause indefinite trouble for the future, he realizes that a great wrong has been committed, and a wrong that could have been easily prevented.

It must also be remembered during sickness that, owing to the fermentation of carbohydrates, colonies of bacteria, and perverted secretions, acids may arise which will be little less effective in destroying tooth structure than medicinal acids. For these reasons, when a patient has any disorder that inflames the mucous membrane, the following precautions should be taken: The mouth should be rinsed with a mild antiseptic wash every four hours. This should be held about the teeth not less than two minutes. When the patient is sufficiently strong to bear the exertion, the teeth should be brushed morning and evening. Evening is the time of greatest danger to the teeth, as the acid mucus during sleep, unless neutralized, will have eight hours of uninterrupted opportunity to attack the enamel. Therefore it would be wise, in addition to the brushing, to rinse the mouth with a teaspoonful of Phillips' milk of magnesia, which will preserve the alkalinity until morning. Should milk of magnesia produce nausea, as sometimes happens, a small piece of lump magnesia soaked in three-per-cent pyrozone will be an efficient substitute. This can be chewed thoroughly and ejected, when the small particles adhering between the teeth will effectually neutralize the acids of the mouth during sleep.

And now for a word or two on the philosophy of lancing the gums of teething children.

When the tooth is ready to erupt it lies in a bony cavity. The crown is fully formed, but the root is unfinished. The lower portion of the root is composed of soft dental pulp that has not yet finished its work of creating the tooth bone that is to give the tooth firm anchorage in the jaw. The alveolar process above the crown melts away by absorption, and the tooth rises up, but when the crown reaches the elastic gum, back pressure at once results, and the tooth is cruelly forced back on the nerve. If the nerve has sufficient vitality, the child suffers no inconvenience and no interference is necessary; but if three or four of these nerves, as frequently happens, receive back pressure at the same time, the irritation becomes manifest. The inhibitory centers are overpowered and the child suffers.

The remedy of course is simple. The gum should be cut down to the tooth, when the pressure will be at once relieved. With molars and canines it should be a cross-cut; with the incisors the incision should be made along the cutting edge of the tooth; but, above all, it must be remembered that the
tooth capsule must be entirely cut through or the pressure will continue.

The lower central incisors come about the sixth month; the upper centrals and upper lateral incisors come at the seventh month, followed rapidly by the lower lateral incisors. The first molars come at the twelfth month, the canines at the eighteenth month, and the last molars come about the end of the second year.

Should the child be well and happy when the teeth are expected, no surgical interference is necessary; but if at this time the child begins to drool, and its bowels become unexplainably deranged, lance where the teeth are expected and lance thoroughly. Do not wait for the gum to bulge or to become inflamed, for the child is already suffering the most terrible toothache and cannot explain. A grown person suffering such pain would bombard the dentist with supplications until relief should be obtained, but the poor little one is only too often left to its fate with the philosophical remark: “Let us not interfere with Nature; teething is a physiological process.”

I feel like apologizing for dwelling on such well known facts, and especially to my esteemed teacher, Dr. Starr, who lectured so well on the treatment of teething children at the University when I was taking my course there, but the great diversity of opinion on this subject must be my excuse.

It is most embarrassing to hear patients say that their doctor will not lance the baby’s gums because the scar will make the gums hard and thereby render the teething more difficult. What is one to say? Scar tissue of all tissue yields most readily to pressure. Then another doctor says he will not lance because the gums are not inflamed. How would a grown person under these conditions like to wait?

One gentleman actually read a paper before our dental society in which he claimed that the pain of teething was caused by septic poisoning of the inflamed gum, and his remarks may be classed with the other crimes that have been committed in the name of bacteriology.

I should also like to protest against the practice of rubbing the teeth through inflamed gum with pennies, thimbles, or similar substances; also against the hard-rubber teething rings which the little ones use in desperation for a momentary relief to the congestion.

In all of these teething disturbances the lancet should be used and used thoroughly. When the gum heals enough to make back pressure it should be reopened, even if the operation has to be repeated several times for each tooth. The intervals of rest for the little patient will make it well worth while. By means of the sharp lancet, judiciously used, and with proper hygienic care in other respects, the gums need never become inflamed, and the disorders incidental to the teething of infants can be in most cases prevented.

TREATMENT OF ISCHOCYMIA.

BY A. L. BENEDICT, A.M., M.D.
Professor of Physiology and Digestive Diseases, Dental Department University of Buffalo; Special Consultant in Medicine, Buffalo Hospital, Sisters of Charity.

In all grades of the motor troubles of the stomach included under the general term “ischocymia,” two indications must always be kept in mind—the weakness and distensibility of the stomach. Although the classification looks to the muscular coat, the condition of the mucous membrane must be accurately known and carefully treated. In most cases hydrochloric acid is deficient or wanting. In the lower grades this deficit may be regarded as usually functional, in the higher grades as usually due to some form of gastric catarrh, and in obstructive dilatation as often cancerous.* Dilatation with chronic gastric catarrh is frequently the accompaniment of cardiac disease or hepatic sclerosis, producing venous stasis in the stomach. With the cardiac disease, or independently, renal disease may exist and may transform the stomach into an eliminating organ. In stomach contents brought to the writer from an out-of-town case, the urinary odor was present, there was effervescence with hypobromite solution corresponding to 3:1000 parts of urea, and a slight precipitate of urates. Experience can never do away with the necessity of carefully noting the exact condition in each case.

Many contraindications are opposed to indications, so that the physician is repeatedly compelled to steer between Scylla and Charybdis. The dilated or sagging stomach needs rest, but it also needs gymnastics; small and infrequent meals will spare the stomach, but at the cost of general nutrition, on which ultimate recovery depends; quickly

* Non-malignant pyloric obstruction with relatively good motor power is usually attended with normal or even excessive secretion of HCl.
digestible foods are apparently demanded, yet these tax the stomach, which is weak, and spare the intestine, which is usually strong; liquid and semi-liquid foods are most easily digested, but they are apt to be too bulky, while dry, concentrated nourishment may fail to pass through the stomach. Water, as a beverage or introduced through the tube, is needed to wash food remnants and mucus from the stomach, yet in too great quantities it weighs down the fundus and aggravates the trouble.

**Diet.**—This subject, on account of the conflicting indications, depends largely on empiricism. If the patient can be kept in bed for a week or two, so as to reduce the demands of the system to a minimum, marked reduction of a dilated stomach can usually be obtained by giving that organ physiologic rest, while feeding by the rectum. The enema used to cleanse the rectum usually furnish nearly all the water needed. Mild astringents and antiseptics such as subcarbonate, subgallate, and salicylate of bismuth, salacetol, benzophenol, etc., may be administered by the mouth. If, for any reason, this course is not feasible, and the patient can abstain from mental and physical work, the best plan is to give morning and evening meals—using hydrochloric acid and papoid or pineapple for digestants rather than pepsin—and resort to lavage a few hours after the evening meal, as necessary. With the use of digestants and such stimulants as strych nine—mainly directed toward the muscular coat—and pilocarpine (0.002 or 0.003 A. C. to increase the secretion), almost any stomach, unless the dilatation is due to organic obstruction, will act fairly well, and may not require lavage oftener than every week or as indicated by malformation. If the patient cannot sacrifice his business interests, it is better to allow a light luncheon of peptonized milk and toasted crackers than to divide the necessary bulk of food into only two parts.

**Milk is not a proper diet for a patient with motor weakness of the stomach, on account of the bulk of an adequate ration and the formation of curds. The possibility of tubercular infection must also be considered. The lack of hemoglobin and other constituents of meat is a contraindication to milk diet not often enough realized by physicians. The pale, shivering, atonic wretches who have been kept on milk diet for months while pursuing their ordinary business, are monuments of self-denial and dietetic heroism and of professional laziness and stupidity. Milk is, however, an almost indispensable article for combination with other foods and for occasional use. If the patient can eat eggs, the problem of diet is much simplified. Beside the ordinary culinary preparations, they may be used as omelet—with or without meat, jelly, etc.—German pancake, salt or sweet; raw, boiled, and baked custard, salt or sweet; egg-water, etc. As at least a dozen eggs daily are required for even moderate nutrition, it is not wise to depend upon them exclusively. The physician must also bear in mind that between a theoretically perfect but monotonous regimen and a varied diet which includes waste matter and even slightly injurious substances, the latter is to be preferred.

Some of the worst cases that the writer has seen have been subjected to a rigid diet, and, as the patients express it, the more they diet the more they have to, and they become as miserable on the restricted regimen as they were before on the most careless choice of food. Heart, crisp salt pork, ham, toasted raw codfish, and all sorts of salt and smoked meats, if not greasy nor too dry, are articles of diet which may be better digested than apparently superior meats. Salt is almost always indicated to aid the hydrochloric secretion. Cereals may be used in moderation. Oatmeal is seldom allowable, as the scales tend to remain in the stomach. Wheat foods must be rejected for the same fault. Farina is excellent, and many preparations of corn, without the seed-coats, may be used. Freshly popped corn—rejecting the scaly parts—is very digestible and contains nearly as much proteid matter as oatmeal. Good soda crackers or saltines may be used, and it is better that all breadstuffs should be dry and toasted. Zwieback seems to be no better than any other stale toast, but it must be remembered that fresh bread, brown on each side and sticky in the middle, is not toast in the dietetic sense. The patient should be warned against heavy vegetables, such as onions and cabbage, against hard parts of all fruits and vegetables, against cakes, pastry, and hot breadstuffs, against tea and coffee—unless used very weak—and against eating or drinking anything so that the stomach shall have more than half a pint or, in mild cases, a pint of contents at once. Water must be taken liberally, to the extent of about two quarts a day—including other beverages, but not water introduced in solid food—but preferably in amounts of not
more than 100 cubic centimeters at a time. Good candy is very nutritious, representing carbohydrate food in condensed form. It will not usually cause distress if the stomach is kept aseptic by hydrochloric acid or, occasionally, aromatic antiseptics, and will not prevent the taking of other food if used as dessert.

After discontinuing rectal alimentation, an excellent diet consists of pancreas sandwiches and pure chocolate candy, but this should not be continued more than a few days without relieving the monotony with eggs and meats. The physician should make sure that the true pancreas is used. Most butchers furnish the thymus or thyroid for sweetbread, and if impressed with the necessity of obtaining the abdominal sweetbread, they may supply the spleen. Beside looking after the quality and quantity of the food, the physician must be careful that rapid eating does not introduce too much air into the stomach, and that foods, proper in themselves, do not ferment. The formation of gas in the stomach tends to stretch the weak muscle and calls for peppermint and other antiseptics, digestive aid, and charcoal as an absorbent. The latter is often given in inefficient dose. It should be thoroughly dried and should be given in not less than half a teaspoonful dose. In judging the thoroughness of gastric digestion, it must be remembered that none of the artificial ferments will accomplish what is claimed for them, and that there is always some residue. For example—as was frequently illustrated by one patient in particular—six hours after a light luncheon the washings may contain a bulky foam consisting mostly of mucus, but containing enough starch or albumin to give the usual tests, and retaining a strong odor of chocolate or any similar aromatic food or beverage. Yet the stomach may be practically empty, and this residue may really be insignificant.

Of late much has been written regarding starch indigestion, both by men obviously influenced by commercial motives and by those who are sincere but whose knowledge of physiologic chemistry is rudimentary. Much of the discussion regarding salivary insufficiency reminds one of the ancient philosophers who argued that a pail of water in which a fish floated should weigh no more than the same pail without the fish. Ewald was unable to find a case of salivary insufficiency, though he examined febrile patients and those with extreme dental caries and oral cancer. If the writers on this subject will experiment with saliva, starch paste, and iodine, they will come to the conclusion that they are on a more hopeless search than was Diogenes. Why, then, does starch indigestion occur, if salivary insufficiency does not? For the simple reason that very few persons masticate and insalivate their food properly. Starch which simply does not digest in the stomach (as in cases of hyperchlorhydria) need do no harm, as normally the bulk of starch digestion is reserved for the pancreas and intestine. Starch or maltose which lies for some time in a foul stomach must ferment—the indication is to keep the stomach clean, not to digest the starch, unless there is evidence of intestinal failure.

In a case of atony or of moderate dilatation or gastropathy, slight regulation of diet and medication directed toward chemical digestion, malfermentation, motor weakness, and general lack of tone are usually sufficient. Tonics must be given cautiously, and frequently cannot be administered in the very cases which most need them. Phosphorus and cod-liver oil can rarely be given to advantage. Unirritating forms of iron, such as reduced iron, Eisenzucker, Blaud's pill, etc., may be given for a week and then discontinued, to be resumed as needed. Arsenic is often of more service than iron, especially if there is need of an antiseptic. Strychnine is practically always indicated to stimulate the gastric muscle, and should be given before meals in about .002 dose. All things considered, it is also the best cardiac tonic, but digitalis and strophanthus may be particularly indicated in some cases, and are best given in tablet form to avoid irritation. Strychnine may well supplant all the simple bitters. Menthol or allied volatile oils and streptopenes may be used both to excite secretion and as antiseptics. Pilocarpine .002 may be alternated with strychnine, for its more specific stimulation of secretion.

The Tube.—In any severe case of failure of motility, the resulting stagnation requires direct cleansing of the stomach. Too often we encounter some such statement as the following: "The patient did not improve while on bismuth and soda, so I tried muriatic acid and gentian; then I gave lactic acid and nux vomica. Meantime he had taken large quantities of peptic, and all without benefit, so I washed out the stomach." It ought to be understood what the tube is to accomplish before the stomach is interfered with, and the failure of previous
measures has nothing to do with its availability, unless to convince a recalcitrant patient. In the treatment of the conditions discussed in this paper the tube is indicated to remove fermenting remnants of food and thus allow physiologic rest—rarely to allow the escape of gas—as well as to cleanse the stomach, and for the purpose of stimulating and healing the gastric wall, by hot baths and medicaments. The too frequent use of the tube abstracts needed nutriment, and the careless introduction of large quantities of water aggravates the condition present.

It is especially in cases of chronic gastric catarrh with dilatation that patients form the habit of using the tube themselves. Such patients empty the stomach at the slightest provocation, not realizing that a moderate amount of fermentation is better than starvation with a clean stomach; they are also usually careless as to the amount of water employed, and, if they use soda to dissolve mucus, they may leave injurious quantities behind. A very practical objection to allowing patients to use the tube is that they soon get to regard the physician as a general adviser, incompetent to order the detailed conduct of their case. With the means of immediate relief always at hand, they will, as a rule, neither refrain from lavage when so directed, nor persevere in the tedious regimen necessary to a cure.

During lavage, particles of food are apt to act as ball valves, allowing the entrance but not the exit of water. Thus, both the inflow and the outflow must be measured in convenient receptacles to avoid accumulation of fluid. However, unless the stomach is absolutely quiescent, a deficit must be expected, about a liter being passed on to the intestine—or perhaps partly absorbed—during one séance. The tube must also be drawn up occasionally to allow the escape of air, a little of which is introduced at each filling and which will accumulate so as to cause discomfort and even strain of muscle, if this precaution is not observed. It is not always possible thoroughly to cleanse a dilated stomach at one sitting, and usually it is not wise to attempt lavage oftener than every day. Turck’s soap or soda may be used to remove mucus and débris, and the latter must be suspended by introducing the water rapidly from a height of three or four feet, the introduction being immediately followed by withdrawal. This maneuver must be repeated at least a dozen times in an obstinate case. The difficulty of removing the cellulose and other débris from the fundus has suggested to several clinicians the use of a double-flow tube. But neither the Y-tube invented in Germany, and reinvented in this country, nor the passage of a small tube within the ordinary stomach catheter, nor the passage of two small rubber tubes side by side, has proved efficient, on account of the narrow space available. The only practical expedient seems to be to include the inlet tube in the wall of the largest sized stomach tube (No. 12 caliber). Unfortunately, the writer has not been able to find an instrument-maker who could put this suggestion into execution. At present, the most practical way around the difficulty is to siphon off the residue while still agitated by the sudden introduction of water.

While the tube is effective as a cleansing agent if lukewarm water is used, water as hot as can be borne stimulates the muscle to contract and indirectly aids the local circulation, and hence the secretion. The alternate pressure and suction upon the stomach also act as a sort of gymnastics. But a gas, on account of its lightness and its expansibility in all directions, affords a better means of exercise than water, however carefully manipulated. Thus, after cleansing the stomach and stimulating it with hot water, the writer practices distention of the organ by means of a bulb. As there is a joint indication for a carminative, the gas usually employed is an oily vapor of menthol or some similar drug. Turck has invented a bag of rubber dam for the sake of preventing the contact of air with the gastric mucosa during this kind of gymnastics, but the device, ingenious as it is, rather detracts from the benefit of the method when medicated vapor is used. At some séances there may be noted a considerable formation of mucus in the stomach—esophageal mucus is easily excluded by its stringy appearance—and in these instances it is wise to substitute for the vapor treatment the introduction of an astringent solution. Silver nitrate may be used, but fluid extract of hydrastis is safer and may be used in more efficient strength, about 10 cubic centimeters being introduced and then diluted with about 250 cubic centimeters of water, posture being employed to get the solution into contact with all parts of the stomach. It is extremely doubtful if the astringent has any effect on the muscular coat.

Turck’s gyromele, to stimulate secretion and also motion on the part of the stomach,
is an instrument which the writer has rather feared to employ, though theoretically valuable. Electricity, as shown experimentally on dogs by Turck and on rabbits by Meltzer, does not produce contractions of the stomach unless under conditions—such as application of one pole to the peritoneal surface—which cannot be duplicated therapeutically. Einhorn, however, experimenting mainly on frogs, claims that something may be accomplished in the human subject, as by using both electrodes within the stomach. His observations, on the whole, confirm those of Turck and Meltzer. The writer some time ago abandoned intragastric faradization from purely clinical impressions as to its uselessness. In a recent case the patient rather urged the use of endogastric faradism. Accordingly, an insulated copper wire was enclosed in a very small rubber tube and passed through the stomach-tube, emerging through a pin-hole opening just below the rubber funnel. A simple manometer was extemporized and connected with the stomach-tube, the unions being air- and water-tight, in spite of the pressure of the electrode. The external electrode was placed sometimes over the stomach, sometimes in the hand. Although variations of gastric pressure could be plainly seen when the patient gagged or breathed, not the slightest movement was evident during faradization. After several trials the patient became convinced of the practical worthlessness of electricity in the stomach.

The frequency with which local treatment of the stomach is needed varies with each case. Cases of simple atony and mild prolapse often require no local treatment; moderately severe cases of ptosis may react favorably to medicinal and dietetic treatment after one or two passages of the tube; marked cases of ptosis and average cases of dilatation require weekly or semiweekly séances at first, with gradual lengthening of the intervals as a cure is approached. The worst forms of dilatation need almost daily lavage, unless fed by the rectum.

Mechanical Treatment.—The writer has elsewhere raised the question whether the improvement in digestion and assimilation often noted in the middle of pregnancy is not due to the support of a prolapsed stomach by the rising uterus. That the stomach is lifted upward by the uterus, quite directly in the late months of pregnancy, indirectly through intestinal pressure in the middle months, is indubitable (see illustrated article in Medicine, 1897). When we reflect how common gastropptosis is in women—some authorities claim that it occurs in ninety per cent of miscellaneous series, the writer finding sagging of the greater curvature, including cases of gastropptosis and dilatation, only in about fifty per cent of digestive cases—and how frequently the nausea and vomiting of the early months of pregnancy are followed by a restoration of the gastric function, not only to the level which it held at conception, but to a normal which the patient has not known for years, the theory that the pregnant uterus may act as a pessary to the stomach gains credence. However, the writer has not the experience with pregnant patients necessary to establish its truth.

The usefulness of artificial supports for the stomach is doubtful. They cannot be applied from below, and a binder, unless very carefully adjusted, will press the stomach downward and backward instead of upward. The interference with intestinal motility may also more than counterbalance the benefit of supporting the stomach. Thus the binder, elastic or otherwise, should be left for cases of hernia, extreme obesity, diastasis of the recti, genuine visceral ptosis, etc. The suspension of garments so as to avoid pressure and dragging must also be considered.

Massage, particularly deep upward kneading of the abdomen, is of value, though futile without internal and local treatment of the stomach.

Surgical Treatment.—Rosenheim has reported several cases in which the inability of the stomach to push its contents through the pylorus was remedied by gastrojejunostomy. In most of the cases the trouble was a malignant growth at the pylorus; in one or two it was non-cancerous. Temporary restoration of motor function followed in all, the stomach contents being expelled in waves through the artificial pylorus, closely imitating the natural process. The malignant disease was delayed for about a year, on the average. Gastrojejunostomy seems also to be indicated in obstinate cases of motor weakness of the stomach, without actual obstruction at the pylorus.

Gastrotrorrhaphy, or the infolding of a portion of redundant stomach wall, has been practiced a few times for excessive dilatation. Bircher reported three cases in 1891; Weir, one in 1892; Borelius, one in 1895, which relapsed and was then relieved by gastroenterostomy. The question as to the disposition of the infolded portion, the fact that the trouble is essentially motor weakness and
not excess of tissue, the tendency to relapse, the fact that cure depends on concentration and stimulation of muscular fibers and that many are sacrificed by the process of infolding—these considerations, as well as the danger of the operation, tend to throw gastrorrhaphy into disfavor.

Ventral fixation of the stomach is a necessary step in gastrostomy. The writer does not know of its employment as an independent operation. Nothing but experiment can determine whether the obvious disadvantages of interfering with the free movability of peritoneal organs can be outweighed by suspending the fundus of a large or sagging stomach. Gastropexy would be theoretically superior, especially if a relaxation of ligamentous support could be demonstrated by diaphany or otherwise. But the mechanical difficulties of such an operation would be almost insuperable.

Karewski quotes Hahn as recommending jejunostomy rather than gastrostomy in certain cases of cancer of the cardia. From theoretical considerations—and there is too little practical experience in this department of surgery to dispense with inductive reasoning—the same operation would seem to be indicated in preference to gastrojejunosotomy, in cases of dilatation of the stomach from malignant disease at the pylorus. The establishment of an artificial anus in rectal cancer is well known to be of benefit not only to prevent obstipation, but to render the development of the tumor slower, by doing away with the impact of feces. Certainly, the less a cancer is stimulated, either mechanically or chemically, the less rapidly will it grow. Even if there were no question of obstruction at the pylorus, jejunostomy might be indicated to afford physiological rest to a stomach with a cancer on the wall. By an ingenious modification of the inlet Karewski claims to have done away with the troublesome leakage from an ordinary jejunal fistula. Thus his operation may be considered in the treatment of obstinate cases of non-malignant dilatation, certainly as an alternative for gastrojejunosotomy. Some surgeons prefer the gastric operations through a misconception of the value of digestion in the stomach. In most cases of severe dilatation and in advanced cancerous disease—that is, in nearly all cases of this general nature in which surgery is to be thought of—the digestive power of the stomach is practically nothing, while malfermentation and autointoxication from the gastric contents is almost inevitable.

Quite recently Einhorn and others have reported cases and have published arguments regarding the various operations to be considered in isochochymia. In general these operations are directed toward the cause of a stenosis rather than toward the motor apparatus of the stomach. Pylorectomy for cancer, some few other tumors, and ulcer, has been performed and is the ideal operation in such instances. In other instances the loosening of adhesions, pylonorplastic operation, or similar interference with the duodenum, is indicated. Whenever the radical operations are not feasible, gastroenterostomy is an easier alternative and one that presents a comparatively low mortality and an opportunity for several months of comfortable existence. Jejunostomy does not yet attract the attention which, on theoretic grounds, it deserves.

ORGANOTHERAPY IN GYNECOLOGY.

BY W. A. NEWMAN DORLAND, A.M., M.D.

ORGANOTHERAPY IN INOPERABLE CARCINOMATA.

Equally as interesting as the history of the rise and development of ovarian organotherapy as practiced to-day, and just as unique, is the record of the influence exerted by organotherapy upon inoperable carcinomata of the genitalia and mammary glands.

The honor of having first directed the attention of the medical world to the efficacy of the proposed plan of treatment belongs to a Scotch physician, Dr. George Beatson,* who in an admirable paper presented at a meeting of the Edinburgh Medico-Chirurgical Society in 1896 suggested that the exciting cause of carcinoma of the breast lay in some pathologic condition of the ovaries. His suggestion was based, primarily, upon the undoubted, though occult, relationship existing between the genital organs and the breast; and, secondarily, upon the fact that the breast is one of the most frequent seats of cancerous disease. It is well known that impregnation and gestation exert a profound influence upon the mamma, resulting in a marked but normal evolution of those organs; and Beatson claimed that it was not unreasonable to assume that in like manner an abnormal stimulus originating in the ovaries might afford an explanation for the development of mammary carcinoma.

Scouting the parasitic theory of carcinoma, as supported by Korotneff and others, Beatson held that the so-called cancer cells would eventually be demonstrated to be in reality germinal epithelial cells. Advancing one step further, he concluded that if it be true that epithelial cells in the ovary and the testicle become germinal cells through some influence in these organs, then by natural sequence extirpation of the ovaries or testicles would exert an inhibitory influence on the proliferation of epithelial cells. Instituting at once a series of investigations upon the human subject on the lines thus laid down, he proved conclusively that removal of the ovaries does undoubtedly influence the growth of carcinoma, though whether only temporarily or not he could not state absolutely. The cases reported by him were, briefly, as follows:

A married woman, aged thirty-three years, had given birth to two children, the elder being three years and the younger one and three-quarters years. During her first lactation there developed a painless tumor in the outer half of the left mamma, which remained stationary in size until her second lactation twenty months subsequently, when it commenced to grow, but was not examined by a physician until ten months later. At that time it measured five by three and a half inches, and had invaded the skin in several places, one of the nodules having ulcerated. The breast was at once removed, but recurrence took place almost immediately in the line of scar tissue, forming a mass adherent to the chest wall with a chain of nodular formation extending into the axilla. Thyroid extract was immediately administered, Beatson regarding it as a powerful lymphatic stimulant, but no good results were noticed, although the treatment was persisted in for a month. At the expiration of that time a double oophorectomy was performed, and one month later the thyroid medication was renewed. In one week's time— or five weeks after the castration—the cancerous masses were smaller and less vascular. In four month's time, the patient taking twenty grains of thyroid extract daily, the main nodule had become a mere yellow lamina not raised above the skin, the axillary growths were smaller, thinner, and yellowish, and the general condition of the patient was excellent. In February, 1896, eight months after the castration, no trace of the cancerous disease could be found, and in June, 1897 — two years after the oophorectomy—the patient remained in a healthy condition.

The second patient was a married nulliparous woman, thirty years of age, a chronic alcoholic, who presented a large tumor of the right breast of five and a half years' duration. The skin was adherent and there was marked axillary involvement and an extension of the disease to the cervical glands, which was associated with more or less stiffness of the neck and jaw. Double oophorectomy was performed, and nine days later thyroid extract was administered in daily doses of ten grains. The pain in the growth had ceased at once after the operation, and at the expiration of two months there was noted a marked decrease in the size of the tumor. The patient then resumed her alcoholism and discontinued the thyroid medication, with a resultant increase in the size of the growth, as noted at the end of six weeks' time. The thyroid treatment was then resumed in daily doses of fifteen grains, with slight improvement, but death eventually occurred from secondary deposits in the liver. In this case it is probable that a more favorable result would have followed an earlier resort to the treatment.

In three other cases of inoperable carcinoma of the breast Beatson noticed a trifling improvement in the local condition, though of but short duration, and consisting mainly in relief of pain and in a lessened vascularity of the growth.

The announcement of this theory of the value of organotherapy in inoperable carcinomatous breast together with its clinical demonstration, startled the scientific world and at once opened up an interesting and suggestive field for further and more extensive exploration. Stanley Boyd* was the next to make a careful study of the new proposition. He applied the treatment in five suitable cases, as follows:

The first patient, aged forty-five years, was suffering from a recurrence of carcinoma in the left breast, the original disease having appeared three and a half years before, and the recurrence being of two years' duration. The growth was adherent to the chest wall at one point, and there was a slight axillary involvement. An extensive operation was attempted, but the entire growth could not be eradicated, whereupon the wound was closed, and five months later a double oophorectomy was performed. The immediate result of the latter operation was relief of pain. At the end of a week the vascularity of the nodules

was lessened, and the general fulness in the pectoral region was much diminished. After four weeks there were noted loss of all pain, reduction of the general swelling and hardness, diminution of the vascularity of all the lesions, disappearance of the red scar-like patches, and disappearance of induration from the floor of the depression resulting from the primary extirpation of the gland. In six months there was practically a cure of the cancerous condition.

The second patient was thirty-seven years old and single. She presented a carcinomatous involvement of the right breast of but three months' duration, although of extensive growth, with adherence to the pectoral muscles. The axillary region had been invaded. A radical operation was performed, but eleven months later the patient returned with a recurrence of the disease in the scar tissue and in the axilla. The patient was thin and anemic, and her general condition was poor. A double oophorectomy was performed, and improvement in the cancerous growth was noted in a week's time. At the end of a month both flesh and color had decidedly been gained. In thirteen weeks the patient had gained eleven pounds, and in twenty-four weeks there was marked improvement in both the local and general manifestations, although the disease was not entirely eradicated.

The third patient had had her left breast removed for carcinomatous disease and had suffered a return of the growth within two years. This continued to develop slowly for four years, by which time there were noted great emaciation and prostration, with pains in various regions of the body, and symptoms of secondary involvement of the liver. Double oophorectomy was performed, and was followed immediately by alleviation of the pain and some diminution in the size of a sternal ulceration, but death occurred fourteen weeks after the operation from the secondary growth in the liver.

The fourth patient was sixty-four years of age and was suffering from extensive carcinous disease of the right breast. Double oophorectomy was performed, but the ovaries were found to be so excessively atrophied that it would be difficult to conceive that they discharged any function or exercised any influence at all upon the rest of the tissues. As was expected, therefore, no improvement followed the operation.

The fifth patient, aged forty-five years, presented a large tumor of the left breast with marked affection of the axillary glands, but associated with a good general condition. Double oophorectomy was performed, together with a wide operation upon the breast and axilla. Three months later the patient was to all appearances in a condition of absolute health.

Boyd thinks that it is in the highest degree improbable that the relationship between the oophorectomy and the atrophy of the cancer masses is other than causal, although he fails to offer an explanation as to the modus operandi. His "working hypothesis is that the internal secretion of the ovaries in some cases favors the growth of the cancer, acting either upon the epithelial cells or upon the surrounding tissues; consequently, in these cases, removal of the ovaries will leave the tissue better able to cope with the parasitic cells."

It was but a step further to conclude that the operation of oophorectomy might just as well influence similarly cancers elsewhere than in the breast, and at the suggestion of Dr. Boyd the treatment was applied in a woman of thirty-five years suffering with extensive cancer of the cervix and vagina. No atrophy of the growth occurred, but the vagina became much more lax, so that examination could be made more readily. Other investigators quickly adopted the method, with varying results. F. Hobday,* of the Royal Veterinary College, obtained definite results in three cases in which the operation was performed upon bitches suffering from offensive papillomatous cancer of the vagina. The idea that ovariotomy might be of value in these cases was strengthened by the observation that during the period of estrum the tumors appeared to grow more rapidly and the discharge to increase in amount. In one instance a normal condition of the vagina developed within a month's time, and in another the discharge ceased entirely. In the third case, in which the tumor was not primarily curedtted, no improvement was noted.

W. Watson Cheyne† operated upon two cases of mammary carcinomata with but temporary success. In the first case, a woman aged thirty-four years, there was a steady improvement for six months, with lessening of induration and diminution in the size of the cancer nodules. The patient was given thyroid tablets irregularly during this period.

---

*British Medical Journal, July 17, 1897.
†British Medical Journal, May 7, 1908.
The growth ultimately assumed renewed activity, and the downward course was progressive. The second case, a woman thirty-two years of age, did not show any improvement worth noting subsequent to the oophorectomy. In the light of his meager results Cheyne suggests that not only should the ovaries be excised, but as much as possible of the morbid growth should be removed at the same time, in order to afford the patient the best chance for absolute recovery. He says that it is quite probable that if too much cancer epithelium be present the removal of the ovarian influence might not produce sufficient alteration in the body to overcome all of the disease.

G. Ernest Herman* emphasizes the fact that thyroid extract exerts a very powerful influence upon the body, and he thinks that Beatson’s method cannot be said to have been followed if the thyroid extract has not been administered. He concludes that cases treated by oophorectomy without thyroid extract do not justify a conclusion as to the uselessness of oophorectomy plus thyroid extract. His explanation of the benefit to be derived from the method is based on the protozoon theory of cancer—that the withdrawal of the ovarian secretion, coupled with the presence of an excess of the thyroid secretion, makes the tissues of some persons a less fit food for the cancer protozoon. He has treated some cases of uterine and vaginal cancer by Beatson’s method, but deems it too early as yet to make a report of the results obtained. In addition, he has operated most successfully upon a case of left mammary carcinoma. Fourteen months later the patient was, comparatively speaking, a well woman.

During the winter three cases deemed suitable for an application of Beatson’s treatment have come into my hands. Two weeks ago, through the kindness of my friend Dr. W. C. Hammond, I was permitted to examine a colored woman, forty-four years of age, who was suffering from an extensive cancerous involvement of the cervix and vaginal vault. She was considerably emaciated and suffered from severe pain and a profuse and offensive leucorrhea. She was informed of the serious nature of her affection, but refused operative treatment until she could hear from her brother, a physician of the South. She was, however, placed on the thyroid treatment, and at once experienced a marked relief of her symptoms—the pain and leucorrhea. She is now taking fifteen grains daily and is showing the good results of the medication. There is no alteration in the size or appearance of the growth.

The second patient, Mrs. W., of Collegeville, Pa., fifty years of age, was suffering from advanced pulmonary trouble, and in addition had an inoperable carcinoma of the left breast which had spread into the axilla. A freely discharging fistulous tract extended from the diseased axillary glands to the anterior axillary line. The patient had been in the hands of a faith-healer for some time and had refused both operative and medical interference. This was a most unpromising case upon which to attempt the method, but her consent was obtained to the administration of the thyroid extract, her general condition not warranting any operative performance. Under the influence of the extract she, in common with other patients so treated, noticed an alleviation of her pain within twenty-four hours, and by the end of forty-eight hours all pain had ceased. This had been her most pronounced symptom, and the relief was so gratifying that she expressed to the nurse her belief that she would have been cured if she had only begun treatment six months earlier. Owing to her weakened condition she was given but 7½ grains of the extract in the day. The relief from pain continued until the time of her death from the pulmonary disease, two weeks after the first dose had been administered.

The third patient, Mrs. H., aged forty-two years, presented a carcinomatous growth of the right breast with a cauliflower-like excrescence the size of a large orange protruding from the upper surface of the gland. The axillary glands were considerably enlarged. She had suffered greatly from the lancinating pains and from the profuse serosanguinous “weeping,” which saturated a number of dressings daily. She had also had one or two large hemorrhages from the under surface of the ulcerated mass. The patient refused to have the knife employed either upon the breast or for the purpose of castration, but readily consented to the administration of the thyroid extract. Beginning on October 11, 1898, with a five-grain tablet three times daily, the treatment has been continued up to the time of writing. After five days of the medication the daily dose was increased to twenty grains, and thenceforth maintained at this amount. Four days after the first dose the patient reported that there was less weeping and much less

* *Lanceet, June 11, 1898.
pain, and stated that the tumor did not feel as heavy as formerly. One week later the under surface of the ulcerated mass showed signs of cicatrization, and the other improvements noted had persisted. Her appetite also was steadily growing larger, and her general condition was good. A profuse hemorrhage occurred three days subsequently, but was promptly arrested by a five-per-cent solution of acenanilid. On November 2 the general appearance of the tumor was healthier, and scar tissue could be plainly seen. Since then the general condition has remained excellent, and although the tumor has not further diminished in size there has been no appreciable spread of the disease. The local symptoms have remained in status quo. On the whole the patient is much more comfortable than before the beginning of the treatment, and her general health has been greatly improved.

The following deductions would appear to be warrantable from a study of the foregoing clinical reports:

1. The ovaries exert a curious and as yet incomprehensible influence over the tissues of the body, and especially over the mammary glands.

2. This ovarian influence is in part neutralized by the action of the thyroid gland or of thyroid substance introduced into the body.

3. The administration of thyroid extract alone to patients suffering from cancer of the mammary gland or of the cervix uteri which has passed beyond the possibility of extirpation by the knife exerts a slight inhibitory action upon the growth, and results in a decided relief of the two prominent symptoms—pain and discharge. This action, however, appears to be but temporary.

4. The removal of the ovaries in cases of inoperable carcinoma, provided these organs be actively functioning, will result in many cases in an arrest of the progress of the malignant disease, or even in a total destruction of the neoplasm and an apparent cure of the condition.

5. This inhibitory action of oophorectomy in inoperable carcinoma is more decided if at the same time as much of the cancerous growth be excised as is possible, and the operations be supplemented by the administration of thyroid extract in full doses.

6. In older women, in whom there has already occurred an atrophy of the ovarian stroma, excision of these organs does not result as promptly nor as favorably as in women who are passing through the period of sexual activity.

7. The relief afforded by the employment of Beattie's method appears in from twenty-four to forty-eight hours, and in favorable cases is rapidly progressive.

8. The dose of the thyroid extract that may be safely employed varies from ten to fifteen grains daily.

9. It would seem that even though this method should not result in an absolute cure of the malignant disease, it would afford a longer lease on life and more effectual relief from suffering than would any other palliative operative procedure as yet devised.

**ELECTROHEMOSTASIS IN SURGERY.**

SKEEN (New York Medical Journal, Feb. 18, 1899), after calling attention to the obvious disadvantages of ligature in the control of hemorrhage, states that his attention was directed to the possible adaptation of electricity to surgical instruments by observing the use of this agency in heating laundry smoothing-irons. An electrical forceps was so designed that a portion of the bleeding tissues could be firmly grasped in its jaws in order to expel as much of the moisture as possible; then this grasped portion was desiccated by heat generated by the electric current. Thus are the walls of the arteries united, and hemorrhage is effectually prevented; the temperature required is not high enough to char or burn the tissues, but simply to cook them. The current required to heat the smallest instrument is two amperes, and eight for the larger, at a pressure of three and a half volts. After the bleeding tissues are seized, and before turning on the electric current, a shield is applied between the forceps and the adjacent tissues, to protect them from injury by contact with the hot instrument. The time required for desiccation varies from half a minute to two minutes, according to the condition of the compressed tissues or size of the arteries; two minutes being required for the ordinary ovarian pedicle and the broad ligament.

The author has employed this method in over 200 celiotomies and in many vaginal hysterectomies and other operations, and has never had a secondary hemorrhage in any of them. The tissues which have become friable by disease and will not hold a ligature are firmly secured by this method; also when the stump is primarily infected it is thus thoroughly disinfected.

The Value of Rest in the Treatment of Cardiac Disease.

If there is one fault in therapeutics to-day above all others, it is the habit on the part of some physicians of employing drugs when other remedial measures will produce equally good results; and it is so much easier to write a prescription than to take the trouble to go into a minute detailed description of a line of treatment which is to be carried out that in many instances the patient receives a medicine and does not receive salutary advice. Perhaps no better instance of the needless use of drugs, when other remedial measures will do equally well, can be deduced than the constant habit of some physicians of prescribing digitalis or other cardiac stimulant to patients who are suffering from various forms of cardiac disease, and too often a few minims of some powerful drug is given three times a day when hygienic measures would benefit the patient very much more.

One of these hygienic measures more frequently employed in England than in this country is rest, in the treatment of valvular disease of the heart. While it is of course true that it is impossible to give to the heart muscle absolute rest, it is nevertheless possible to protect it from a large amount of unnecessary wear and tear, and we have come to regard absolute rest in bed with massage and gentle Swedish movements as being of far greater benefit to most patients who are suffering from valvular disease with associated failure of the circulation than is digitalis or any similar drug.

Those who have ignored this important factor, rest, in the treatment of cardiac disease, will we are sure be greatly surprised at the relief of the symptoms, both acute and chronic, which have brought the patient into professional care, even though no drug be given. In some instances it is wise to begin the treatment, after the patient has had twenty-four hours' rest in bed, by the administration of some fairly active cathartic which will unload the liver, which is very apt to be engorged with blood in cases of failure of circulation, and also to administer tonic drugs such as minute doses of quinine and arsenic for their beneficial influence upon the blood itself and upon nutrition in general. The patient ought to be sponged freely with alcohol and water, with active friction, preferably at night just before going to sleep, as this sponging will keep the skin clean, improve the peripheral circulation, and by allaying peripheral nervous disturbances cause the patient to sleep more comfortably.

Where the action of the heart remains excited and transmits a heaving impulse to the chest wall, advantage may be gained by applying to the patient's precordium an ice-bag partly filled with small pieces of ice, which, because of its being partly filled, fits snugly to the chest wall and does not readily fall off when the patient changes his position slightly.

Sometimes it is necessary, instead of administering small doses of digitalis, to give these patients small doses of aconite to put aside excessive cardiac action.

The Abuse of Quinine.

Apropos of the editorial bearing this title, which appeared in the March issue of the Therapeutic Gazette for the current year, and of the Progress item taken from the Medical Record and published in our pages, it is interesting to note that the discussion in
regard to, the value of quinine in malarial hematuria has been waged with even greater activity than before.

The great difficulty that many men seem to labor under in discussing a medical subject is an inability to realize that a drug capable of doing an infinite amount of good under certain circumstances is also capable of doing a similar amount of harm under others. This is our whole contention in this matter. It is not to antagonize the use of quinine in malarial infection unless there be side by side with that condition some state which renders the administration of this remedy inadvisable. It would seem evident that in some cases in which blood is in the urine, quinine certainly does no harm and perhaps may do good, but the evidence is convincing that in other cases it does a vast amount of damage. The proper attitude for the practicing physician to take is not that of one willing to entirely cast aside this valuable drug, nor of one who is willing to use it as a panacea for every case, but rather that of one who determines the fitness of the drug to perform certain functions. In a number of instances protests against the position taken by the Medical News in regard to this question have appeared. One of them is published in the correspondence columns of the News of March 18 by Dr. Colomb, of Louisiana, and we are glad to see that in the editorial reply to this letter the Medical News is after all coming to the position which we occupy ourselves, namely, that the drug is not to be used freely in every case. Certainly the dictum of the Medical News that "quinine should be used freely whenever malaria is clearly present, no matter what the complication," is too far-reaching.

The North Carolina Medical Journal of March 5, 1899, also contains a series of interesting papers upon this subject. In the first of these, Dr. Lewis, of Jackson, North Carolina, stated that he gives quinine in malarial hematuria, but he wishes it understood that he advocates medium doses, just sufficient to prevent another paroxysm, and he makes the additional suggestion, which we think is wise, that the quinine should not be given by the mouth until the stomach is retentive and the urine clear. He concludes his article by the following summary:

"1. Protect against another chill with quinine hypodermically administered once every twenty-four hours, until the urine clears and the stomach is quiet. Give morphine with first dose of quinine, and keep patient gently under its influence until he improves.

"2. Give high rectal injections of normal salt solution from the first. Repeat them every four or six hours, until convalescence is assured. Inject normal salt solution under the skin for threatened suppression of urine, uremia, or collapse.

"3. Move the bowels frequently with calomel and phosphate of sodium. Avoid over-purgation; give nitrohydrochloric acid after bowels act.

"4. Control temperature with cold sponging. Rely on morphone hypodermically for nausea and persistent vomiting.

"5. Keep patient in recumbent position. Withhold all food for twenty-four hours—but give all the water, hot or cold, the patient will take.

"6. Nourish by the stomach after twenty-four hours, if possible; if not, by the rectum.

"7. Give quinine in small doses until complete convalescence. Put patient on blood tonics; see to the quality of his food, drinking-water, and clothing."

Another article on the same subject in the same issue of the North Carolina Medical Journal, by Dr. White, of Belvidere, North Carolina, states emphatically that hemorrhages are due to the improper and prolonged administration of quinine in a system unable to receive it. When he is called to a case he immediately gives a hypodermic injection of morphone and atropine to relieve the nausea, vomiting, restlessness, and pain, and applies counter-irritation over the stomach, liver, and kidneys; gives a twenty-grain dose of calomel, and follows it in twelve hours by an enema; and if the hematuria persists, in twenty-four hours more another twenty-grain dose of calomel is given. He also administers three grains of nitrate of potassium well diluted every three hours until the urine becomes clear, and he uses saline and Fowler's solution as a tonic and stimulant, supporting the heart with strychnine, digitalis, and hot bottles, and giving hot liquid nourishment. He concludes his article by saying that during the first two years of his practice he considered this disease a pernicious malarial fever, and treated it accordingly with large doses of quinine, and all his patients died. He then abandoned the quinine and had much better results.

The third paper in the same issue, by Dr. Mann, of Nashville, North Carolina, indicates that he does not employ quinine in this stage of the disease, for he tells us that he never employs it until the patient's urine is cleared up and the sick stomach has disappeared,
and then in very small doses. He also gives full doses of calomel, copious draughts of water containing bicarbonate of sodium, digitalis, and applies hot bottles over the kidneys. In other words, he endeavors to relieve the renal difficulty as much as possible.

ARE THE SALICYLATES USEFUL REMEDIES IN TRUE GOUT?

There is no class of diseases of which we know so little in respect to their etiology and pathology as those which are classed as diathetic, or in other words, dependent upon some disorder in the nutritional processes which we call metabolism. Because of this ignorance the use of all of our remedial measures for this class of cases is to a great extent empirical and unsatisfactory, and the exhaustive studies of the last few years made by Garrod, Haig, Luff, and others, while seeming to promise far more satisfactory knowledge of these diseases, have not advanced as far as the practical clinician and therapeutist desires. That the disease, gout, does depend upon faulty metabolism, and that as a result of this fault uric acid is formed in the body in excess, is proved, but the causes of the faulty metabolism are undiscovered, and therefore our methods are chiefly devoted, aside from diet, to its relief rather than the cure of the malady. It is not our intention at this time to attempt to discuss the very important question of the pathology or pathogeny of gout; on the one hand we find a nervous origin urged, and on the other that an accumulation of uric acid is the factor to be combated. Much of Haig's suggestive work, however, is based on hypotheses which do not seem to us to be founded upon fact, and certain of his experiments, accurate in themselves, are equally hypothetical in origin. If, as he claims, uric acid in excess is the cause of the attacks of gout, we should have theoretically a most sovereign remedy in salicylic acid, but as a matter of fact it very often fails, and a decision as to its anti-gout powers is to be sought therefore more in clinical observation than in experiment.

About this point opinions differ most essentially, some clinicians asserting that the salicylates are most efficient, and others teaching that they are futile. Thus Germain Sée and Jaccoud believe them superior to colchicum, whereas Sir Dyce Duckworth, Barclay, Ebstein, and Lécorché believe the salicylates less valuable.

It is evident at once in studying this matter that we must divide it into two parts, namely, as to the value of the salicylates in the acute attack, and as a remedy for the condition between the attacks and for the cause of the attack.

In respect to the attack Duckworth reports that he has tried sodium salicylate in a considerable number of cases of acute gout and finds it very inferior to colchicum, and inquiry among his friends elicited a similar conclusion. He has, however, seen it do great good in a few cases in which colchicum failed, but he cannot predicate which will be benefited. Ebstein thinks that under the salicylate treatment the manifestations of the attack simply shift from joint to joint. Lécorché asserts that while salicylate of sodium often relieves the pain of gout, it does not shorten the attack, nor does it prevent subsequent attacks, although he asserts that its use in full doses of one to one and a half drachms increases the elimination of uric acid in the urine, and Henri Souiller asserts that the salicylates are the best remedies if the kidneys are intact.

THE SURGICAL TREATMENT OF GOITRE.

As a result of what is now an enormous experience in the surgical treatment of goitre, not only has the technique of operation been simplified and the mortality greatly lowered, but the indications for operation have become considerably extended, and the choice of methods has been fairly well crystallized. Reverdin has collected records of 6103 operations. The mortality is less than three per cent, in marked contrast to Liebich's statement that before 1851 the mortality was over thirty-one per cent.

The choice between general and local anesthesia should be founded on general principles. Reverdin very justly holds that in the case of a simple goitre, not complicated by symptoms of dyspnea, there is neither danger nor inconvenience in the administration of a general anesthetic, and under such circumstances ether is the agent to be chosen. In grave cases it may be necessary to operate either without an anesthetic or by means of local anesthesia. Socin has practically abandoned general anesthesia and practices the operation entirely under the influence of cocaine infiltration. The only painful part of the operation is, he states, that attendant upon the section of the sub-
hyoidean muscles. In his last 110 operations Socin used local anesthesia ninety-one times, chloroform nineteen times. He has completely given up ether. Roux, who has personally operated on 526 cases, has abandoned all anesthesia, holding that thus the operation is rendered bloodless, and that the sensations of the patient are valuable in aiding the surgeon to avoid structures which should not be injured.

Exposure of the tumors by transverse incision is the method of choice. The sternomastoid muscles are retracted; the sternothyroids are either separated or divided, after which there is seen an aponeurotic envelope which must be cut through before the proper capsule of the tumor is reached.

The total extirpation has now been completely abandoned. In the partial extirpation, the principal operative danger is dependent upon the fact that the recurrent laryngeal nerve may be injured when the inferior thyroid is ligated. The enucleation, which is with Reverdin the operation of choice, consists in cutting through the layer of glandular tissue enclosing the cystic or solid tumors, and enucleating them by means of the finger, or by blunt instruments. Reverdin finds that partial extirpation gives a mortality of 3½ per cent, whilst in intraglandular enucleation the mortality is less than one per cent.

The causes of death are mainly incident to respiratory complications, though tetany, myxedema, hemorrhage, and septic infection also figure in the mortality columns.

Enucleation has not been followed by death from hemorrhage, septicemia, or from tetany or myxedema. The primitive hemorrhage is usually insignificant. The recurrent is less likely to be wounded, and after enucleation the neck preserves a more normal appearance than after a partial extirpation.

All operations may be followed by recurrence. When the tumor cannot be treated by enucleation, partial extirpation is the method of choice. Reverdin believes that when the goitre is acutely inflamed it should be extirpated, if seen at an early stage of the infection; should be incised, if seen somewhat later.

Socin agrees with Reverdin as to the advantages of enucleation. Of 300 operations, he notes that in thirty-six abscesses developed due to staphylococcus. Roux particularly insists upon the importance of beginning the direct attack upon the goitre by first ligating the superior thyroid artery, then passing a loop about the isthmus so that in case tracheotomy should be necessary the trachea can be freed immediately and a tube inserted. In all difficult cases every preparation should be made for such a tracheotomy. When there is much bleeding following enucleation, he ligates the inferior thyroid. When the goitre is acutely inflamed, Roux strongly advises against any more formidable intervention than that by incision. Of 235 goitres recently operated upon, Roux has lost but three. Girard has lost six cases out of 545 operations, three from cardiac syncope. Doyen performs thyroidectomy in from five to six minutes; ten minutes is his maximum.

These communications to the Congrès Francais de Chirurgie represent fairly well not only the enormous number of goitre operations performed in Europe, but the admirable results obtained from these operations in the hands of many different operators, and the absence of the disagreeable sequels attendant upon the earlier complete removal of the gland. Not only does the cystic or solid goitre form an unsightly and cumbersome tumor, but it is almost invariably accompanied by nervous and circulatory disturbances, which are more or less crippling. Aside from its cosmetic value, the operation is usually attended by a rapid and most marked improvement in general health and activity. It is well to have these facts repeatedly brought to the attention of physicians, until, recognizing how safe and satisfactory the modern operation is, they make surgical intervention as popular here as it is abroad.

WOUNDS OF THE PERICARDIUM AND HEART.

Loison prefixes an admirable study upon this topic (Revue de Chirurgie, Nos. 1, 2, and 3, 1899) by a quotation from Legouest, to the effect that no topic seems more interesting than the history of wounds of the heart, but that there is in reality none which offers less of interest, since the whole subject is covered by a few curious and authentic facts, others more or less doubtful, an uncertain symptomatology, hopeless therapeutics, and an almost invariably fatal termination.

With the idea of disproving to a certain extent this summarization of the subject, Loison has collected the cases reported since Fischer's memoir published in 1868, and based upon 452 observations. Two hundred and twenty-seven cases were collected, giving
a total mortality of 84.8 per cent, which corresponds almost precisely with Fischer’s mortality.

The cases are arranged in four tables, the first of which includes wounds by needles, the second wounds by puncturing and cutting instruments, the third gunshot wounds, and the fourth rupture on contusion.

Of twenty-three cases of needle wound, thirty-nine per cent recovered; in a number of cases the needle was withdrawn; in one instance it was not seen until after the pericardium was opened, when the extremity was observed in the right ventricle. The muscles were superficially incised, but the needle buried itself still more deeply at each systole and could not be withdrawn. In another case, after resection of the fifth rib and opening of the pericardium, the needle was distinctly seen penetrating transversely the right ventricle, but could not be extracted. The case recovered.

In ninety cases of stab wounds there were but eleven recoveries. One of these was without intervention; three got well after incision and tamponing the pericardium; two after incision and drainage of the pericardium, which had been attacked by secondary suppuration; three after suture of the pericardium; one after suture of the heart and drainage of the pericardium; and one after suture of the heart and of the pericardium. Twenty-three of the ninety cases were subject to surgical intervention.

Parozzani’s case was one of the most brilliant. The patient had been stabbed in the seventh intercostal space in the left mammary line. An L-shaped flap was raised, and the fifth, sixth, seventh, and eighth ribs were resected. A wound of the lower part of the pericardium was observed from which was issuing blood. The pericardium was opened by a 2½-inch incision, and a wound was then observed at the extremity of the left ventricle from which spurted a jet of blood at each systole. By means of four silk sutures the wound in the heart was closed. After this the opening in the pericardium was secured by six sutures, whereupon the flap, made up of the ribs and soft parts, was secured in place, and about three pints of artificial serum was injected subcutaneously. This patient recovered completely.

These results prove that in a limited number of cases surgical intervention in wounds of the heart might be as distinctly indicated, and, if timely, as completely successful, as it is in wounds of the abdominal viscera.

**Reports on Therapeutic Progress**

**TREATMENT OF PHARYNGITIS.**

The *Journal des Praticiens* of December 10, 1896, quotes Castex as dividing pharyngitis into two groups, namely, the acute and chronic. The acute form can again be divided into the simple and catarrhal variety and the septic and phlegmonous.

In the treatment of the simple form hot antiseptic atomizations with borated, phenolated, or mentholated solutions are useful, particularly if at the same time a hot vapor bath is taken and some quinine is administered. The following prescription is also suggested to be taken internally:

- Antipyrin, 45 grains;
- Syrup, 1 ounce;
- Distilled water, 4 ounces.

This may be divided into several doses and taken in the course of twenty-four to forty-eight hours. In other instances the following prescription is useful:

- Tincture of aconite, 20 drops;
- Syrup of codeine, 6 drachms;
- Syrup of tolu, 6 drachms;
- Aromatic elixir, 4 ounces.

Two teaspoonfuls to a tablespoonful of this is to be taken every hour until the pulse shows markedly the influence of the aconite.

In the septic form of pharyngitis, copious applications of antiseptic solutions, containing carbolic acid or salicylic acid in the proportion of one per cent, are to be employed, and alcoholic stimulants, with intestinal antisepsis, is to be resorted to. If the case is exceedingly septic, it may be wise to use antistreptococcic serum to prevent suppuration.

Chronic pharyngitis is to be treated by general and local measures. The following tablet may be allowed to dissolve in the mouth:

- Chlorate of potassium, 3 grains;
- Extract of eucalyptus, 1 grain;
- Powdered cubeb, 3 grains.

These are mixed with any fruit paste in sufficient quantity to make a pastille, and two to three are to be used before speaking or singing.

In the congestive form gargles of antiseptics or atomizations of hot liquids are useful, and should there be a tendency to lack of secretion and induration of the part, the following may be applied by means of an applicator:
Iodine, 15 grains;  
Iodide of potassium, 45 grains;  
Distilled water, 1-2 ounces.

If granulations are present they should be treated by the electric cautery. Hyper-trophies must, if necessary, be removed by curetting, and internally the bromides may be needed; but as a rule hydrotherapeutic measures, designed to increase vascular tone, are advisable. Often a visit to some hot spring with alkaline waters is useful.

THE TREATMENT OF LARYNGEAL TUBERCULOSIS.

The Journal des Practiciens of December 3, 1898, contains an article on this subject, which, after pointing out the unfortunate condition of the patient suffering from this malady, proceeds to the consideration of the various measures which can be instituted for its relief. These methods may be divided into four groups, namely, the treatment by atomization, insufflation, inhalation, and direct application.

Hot vapors, or atomizations, are particularly useful in the congestive period of the disease. They are best used by placing the medicament in boiling water, through which air is drawn by the patient by inhalation, as is carried out, for example, in the various inhalers which can be found in most drug stores. Of the antiseptic fumigations, the following may be mentioned:

- Carbolic acid, 15 grains;  
- Distilled water, 3 ounces.
- Benzoate of sodium, 30 grains;  
- Distilled water, 3 ounces.
- Boric acid, 45 grains;  
- Distilled water, 3 ounces.
- Menthol crystals, 15 grains;  
- Tincture of eucalyptus, 2 drachms;  
- Alcohol, 2 ounces;  
- Distilled water, 5 ounces.
- Benzoate of sodium, 2 drachms;  
- Boric acid, 1 drachm;  
- Glycerin, 2 ounces;  
- Distilled water, enough to make a pint.
- Crystalline carbolic acid, 15 grains;  
- Glycerin, 2 drachms;  
- Decoction of marshmallow and poppy, 10 ounces.
- Oil of eucalyptus, 45 minims;  
- Alcohol, 2-3 ounces;  
- Distilled water, 6 ounces.

Sometimes these liquids can be used in an atomizer rather than by inhaling them in steam or moist air, but in some patients, atomization causes too much irritation and seems to augment the inflammation of the larynx. In these cases sedative nebulations are necessary, such as:

- Hydrochlorate of cocaine, 7 grains;
- Hydrochlorate of morphine, 7 grains;
- Cherry-laurel water, 2 drachms;
- Neutral glycerin, 1 ounce;
- Distilled water, 10 ounces.
- Hydrochlorate of cocaine, 7 grains;
- Carbolic acid, 7 grains;
- Cherry-laurel water, 2 ounces;
- Neutral glycerin, 2 ounces;
- Distilled water, enough to make a pint.
- Hydrochlorate of cocaine, 4 grains;
- Chloral, 45 grains;
- Bromide of potassium, 30 to 60 grains;
- Glycerin, 2 ounces;
- Distilled water, 10 ounces.

In some cases the cocaine may be well replaced by carbolic acid or creosote.

- Hydrochlorate of cocaine, 30 grains;
- Hydrochlorate of morphia and antipyrin, of each 15 grains;
- Neutral glycerin, 2 ounces.

Of this a teaspoonful is to be put in half a glass of distilled water and atomized. Or,

- Hydrochlorate of morphine, 3 grains;
- Bromide of potassium, 2% drachms;
- Water, 3 ounces.
- Arsenate of sodium, 2 grains;
- Hydrochlorate of morphine, 2 grains;
- Glycerin, 2 ounces;
- Water, 3 ounces.
- Bromide of potassium, 3 drachms;
- Hydrochlorate of morphine, 2 grains;
- Cherry-laurel water, 2 ounces;
- Distilled water, 1 pint.

Of the preparations which may be used for insufflation, we find that the following drugs are most commonly applied: Iodoform, aristoil, iodol, salol, dermatal, alum, tannic acid, and acetate of lead, all these being incorporated with sugar of milk. Of the pain-relieving insufflations, mention may be made of:

- Hydrochlorate of morphine, 1-2 grain;
- Sugar of milk, 30 grains.
- Gum arabic, 15 grains.
- Extract of belladonna, 1-2 grain;
- Powdered alum, 2 grains;
- Powdered white sugar, 2 grains.
- Iodoform, 45 grains;
- Oxide of zinc, 30 grains;
- Morphine, 2 grains.

Of the inhalations of balsamic substances which combat the fetid odor, much can be said. We may mention turpentine, menthol, balsam of Peru, and essence of pine, all of which may be used by soaking a tampon with them and placing it in an ordinary pipe through which the air is drawn; or in other cases these medicaments may be added to hot water, and the steam laden with them inhaled.
A large number of substances can be used for direct application, but nearly always this requires the skill of a competent laryngologist.

Finally, mention is made that in the papers of Rozenberg intralaryngeal injections with a special syringe are recommended; the injection consists of:

Menthol, 6 drachms;
Sterilized olive oil, 3 ounces.

A small quantity of this is injected into the larynx.

ASTHMA AND ITS TREATMENT.

The British Medical Journal of December 24, 1898, contains an article on asthma written by Sidney Martin, in the course of which he says that in considering the treatment of asthma it will be convenient to limit the discussion to the primary spasmodic form uncomplicated by bronchitis, and to the form associated with bronchitis, whether this be bronchitic asthma—that is, bronchitis preceding the asthma—or a case of primary asthma complicated later by chronic bronchitis. In the latter case the treatment is that of bronchitis as well as asthma; in the former it is that of asthma alone.

It is to be remembered that the attacks of asthma may begin suddenly and cease suddenly; and their sudden cessation is due, as a rule, to no medical treatment; but to some sudden excitement, shock, or some change of life, or to a change of locality. This applies chiefly to those cases uncomplicated with bronchitis. The sudden stoppage of the attacks, even for months, does not preclude their recurrence; indeed, they usually recur. Each case of asthma has its peculiarities as regards the manner in which the attacks are influenced by locality, food, and mode of life.

In discussing the treatment it must be borne in mind that although it is probable that spasm of the bronchial tubes is the immediate cause of the respiratory symptoms, in some cases the attacks are associated with peripheral irritation (inhalation of pollen, disease of the nasopharynx, indigestion of food, etc.), and that in all cases of asthma, although to a varying degree, there is a functional disturbance of the central nervous system and of the respiratory center.

Sedatives.—It is necessary to treat the asthmatic attack; the patient demands it, and the condition requires it. In uncomplicated asthma sedatives will cut short the attack, such as the hypodermic injection of morphine (¼ to ½ grain), the administration of chloral, or the inhalation of chloroform. The effect of the latter is evanescent, and it is not to be compared in efficiency to either morphine or chloral. The use of morphine or of chloral is to be limited to the attacks, is not to be continued for too long a period, and must be in the hands of the practitioner and not of the patient.

Inhalation.—The inhalation of the fumes of burning niter paper or specially prepared powders, or of cigarettes, is the popular remedy for the attacks of asthma. In many cases they give relief, in some marked relief. The powders consist of stramonium and niter chiefly; the one which Dr. Martin uses at the hospital contains one part each of anise and niter, two parts of stramonium leaves, and five grains of tobacco, to the ounce; one teaspoonful is to be burnt on a plate and the fumes inhaled. The cigarettes used are a manufactured article containing stramonium leaves, niter, and tobacco; they relieve the attacks sometimes when the powder fails. A pill containing $\frac{3}{6}$ to $\frac{3}{4}$ grain of morphine, with $\frac{1}{10}$ grain of atropine sulphate, given at bedtime, is sometimes useful. Extract of stramonium ($\frac{3}{4}$ grain) may be substituted for the atropine. Martin has not found the ethereal tincture of lobelia very useful; but he says he has not tried it in the way recommended by Hyde Salter, namely, in repeated small doses before the attack is expected.

Treatment of the General Condition.—The relief of the attacks of asthma is a necessity, inasmuch as repeated attacks not only seriously curtail the business and pleasure of life, but conduce in the pure spasmodic form to the suppuration of bronchitis and emphysema. The use, however, of sedatives, such as morphine and chloral, and of inhalations, constitutes no treatment of the disease, and must be limited as much as possible, especially in the uncomplicated form of asthma, while efforts are made to benefit the general condition of the patient. Harm is frequently done by the indiscriminate use of inhalations, predisposing as they do by their irritant nature to the suppuration of bronchial catarrh. Of remedies which may be continuously administered to patients who have frequently recurring attacks, two are most constantly used, namely, iodide of potassium and arsenic. The iodide may be most conveniently given with stramonium, as in the mixture in the Hospital Pharmacopeia, which consists of a quarter of a grain of extract of
stramonium, two grains of extract of licorice, three grains of iodide of potassium, and five minims of chloric ether. This mixture may be given two or three times daily in cases of asthma, and in many instances with benefit. In some cases, indeed, although not usually, it promptly stops the attacks. It possesses two drawbacks. The stramonium leads in some cases to paralysis of accommodation, which is detrimental to the carrying on of the person's occupation. But by diminishing the dose the patient soon ceases to experience discomfort from the remedy, and Dr. Martin says he has not yet seen an asthmatic who did not prefer stramonium, with its drawbacks, to the disease. Some asthmatics, especially those of a highly neurotic temperament, are very susceptible to the action of stramonium; Dr. Martin has seen doses of even \( \frac{1}{4} \) grain of the extract produce dryness of the throat and a state of nervous excitability which necessitated the stoppage of the drug. He thinks if patients can take stramonium with the iodide they do better than with the iodide alone. If given alone, the iodide must be administered in five-grain doses two or three times daily, the medicine being stopped from time to time. Arsenic by itself in doses of three minims of the liquor arsenicalis is a useful remedy for continuous administration in asthma, and it may be combined with iodide of potassium (three to five grains) in a mixture.

Peripheral Irritation.—The treatment of local conditions which act as peripheral irritants in cases of asthma need not be discussed at length. With regard to the nasopharynx, the presence of a nasal discharge (watery and mucoid) in cases of asthma other than hay-asthma is by no means uncommon, but is not always associated with serious local disease. The insufflation of a solution of bicarbonate and chloride of sodium, if there is much nasal secretion, is frequently of service, and the application of cocaine in such cases to the nasal mucous membrane is described by the patients as helping to relieve the attacks. Application of the cautery in some cases relieves hay-asthma. In children with large tonsils or with adenoids, in whom asthma supervenes, the surgical treatment of the local condition, although it may be necessary, does not of itself cure the asthmatic attacks, which may persist for months after the faucæ and pharynx have been successfully treated. The removal of a nasal polypus may greatly relieve the attacks, but not a few cases persist after removal.

Diet.—Chronic asthmatics—that is, those in whom the attacks have lasted for some months or years—are frequently the subject of indigestion of food, as shown in the symptoms of weight and discomfort after food, and flatulence. This is sometimes the result of overdressing. In the cases of peptic asthma the regular attacks of the disease occur after a meal, usually the heaviest meal in the day, and are associated with indigestion of food. The regulation of the diet of asthmatic patients is of great importance; meals ought to consist only of digestible food, and that in moderate quantity, no heavy late meals being allowed. Remedies such as alkales after meals, given with the view of correcting the indigestion, combined with a proper diet, give great relief to cases of peptic asthma. Although the asthmatic ought to be careful as regards the food taken, it is wrong treatment to starve such a patient; only harm can come of it, inasmuch as the best chance of the patient recovering is an improvement of his general health, and this cannot occur without a sufficiency of food. It is for this reason, doubtless, that cod-liver oil does so much good in some cases when every remedy seems to have failed. The improvement if the oil can be taken is sometimes very marked, rendering possible the diminution, or even cessation, of the inhalations which the patient considered his sheet-anchor.

The confirmed asthmatical adult can only be relieved, and that sometimes very imperfectly, by the methods which have been detailed; and indeed in some cases all treatment appears of as little avail as in confirmed epilepsy. It is quite otherwise with the asthma of children under the age of ten years, at which time a large number of cases arise. By treating the attacks by a careful regulation of the diet and mode of life of the child, and by the avoidance of any "hot-house" treatment over a number of years, the asthmatic child loses his attacks without serious damage to the respiratory apparatus.

THE "TRANSACTIONS" OF THE SOCIETY OF ANESTHETISTS OF ENGLAND.

From a perusal of the published "Transactions" of the Society of Anesthetists of Great Britain, one will, of course, gather much instructive and practical information; but at the same time one can hardly forbear to notice the difference of opinion that exists between skilled anesthetists, both as regards
the anesthetics to be used and the manner of administering the same. Owing to the large number of fatal results following the giving of chloroform, that drug has undoubtedly, even in Great Britain, fallen into a certain degree of disrepute as an anesthetic, and ether has correspondingly risen in the estimation of medical men as a safer means of producing unconsciousness. Nevertheless the upholders of chloroform still contend—and probably rightly enough—that the danger is not so much in the chloroform itself as in the manner of its administration. Mr. Tyrrel, when reading a paper before the Society, and commenting on the many writers to medical journals nowadays who conclude their communications by saying that they have never had any difficulties with ether, appositely remarks: "When I read these letters I feel like Mr. Underwood, who was instructing a student at the Dental Hospital of London how not to break a tooth in extracting it, when the student said that he never had broken a tooth, and Mr. Underwood said: 'I am sorry for you; your experience hitherto must have been extremely small.' And this is what I feel when a man rushes into print to say that he has never had any difficulty with ether." Mr. Tyrrel is also not in favor of the A. C. E. mixture, but uses an adaptation of his own of the "double-bottle method," by which chloroform can be administered and ether added as required for the particular case under treatment. This method is said to act very well in the hands of a skillful administrator, although it is yet to be proved that ether increases the action of the chloroform. We should be rather of the opinion that its action is that of a stimulant to the patient.

The paper read by Mr. Alexander Wilson, on resuscitation in emergencies under anesthetics, is a clear exposition of the subject, but is much too lengthy to be more than briefly noticed. To one point we would, however, draw attention—to the habit of injecting strychnine to counteract the ill effects of chloroform. For some time past Dr. Silk has been accustomed to give strychnine in all cases in which he contemplated a severe operation, injecting a small quantity (one-twentieth grain) immediately after the induction of anesthesia, and repeating the dose once or twice if necessary. Recently in the British Medical Journal it was reported that as much as half a grain of strychnine had been given in a case of chloroform poisoning; and in the same journal a writer stated that when he used strychnine as an antidote to chloroform overnarcosis, he gave at least fifteen minims of liquor strychnini. This would seem to show the importance of giving fairly large doses, in order to get any counteracting effects. Dr. Dudley Buxton, the president of the Society of Anesthetists (speaking on the question of the methods to be used in administering anesthetics, and in answer to questions by Dr. Cook inquiring whether the pouring of chloroform on lint, or A. C. E. mixture in Rendle's inhaler, which allowed the ordinary air to be mixed with it, was not an unjustifiable method in the light of recent exact experiments and the results obtained from them), said that he (the President) could not sit in judgment upon methods which others had seen fit to employ, nor could he go so far as to say whether or not any methods were unjustifiable. His own personal feeling was that any method which did not admit of exact or nearly exact dosage was faulty, and that faultiness would sooner or later appeal to those who used it in a most unpleasant way. One had also to remember that no less an authority than Lord Lister had stated that an exact dosage could not be guaranteed by the employment of lint or a towel on which chloroform was dropped, believing as he (Lord Lister) did that, knowing the temperature of the air and therefore the rate of evaporation, no one could tell at what rate the anesthetic was inhaled. Personally he thought the experiments from which the dictum was made were open to grave criticism.

It will be seen from the foregoing that the feeling in Great Britain leans toward the use of ether; that it is now generally recognized as a safer anesthetic than chloroform; and also that medical men are gradually but surely becoming conscious that methods whereby exact dosage can be guaranteed are far safer than the old haphazard modes of administering anesthetics.—Medical Record, Dec. 31, 1898.

 PROTARGOL AND ARGONIN IN THE TREATMENT OF THE PURULENT OPHTHALMIA OF INFANTS.

The Medical News of January 21, 1899, contains an article by Peck in which he describes his views as to the value of these new drugs in this serious malady in infants.

Dr. Peck says his only motive for presenting this brief paper is to emphasize the following points in connection with the two remedies, protargol and argonin, in so far as
they seem to be superior to silver nitrate. These points are: (1) the quicker destruction of the gonococcus; (2) the earlier disappearance of the secretion and the inflammatory process; (3) the resolution of the injured corneal and conjunctival tissues.

A brief chemical review of these two agents is necessary in order to understand their clinical relations. Each is described as a silver proteid compound, solutions of which cannot be precipitated by sodium chloride, or by albuminous fluid.” Protargol contains 8.3 per cent of silver; it is a yellowish powder, readily soluble in cold as well as in hot water, forming a clear solution. Argon contains 4.2 per cent of silver; it is also a powder, being fine, white, and readily soluble in water on gently warming, but its solution is turbid. Argon decomposes if exposed to too much heat in the preparation of solutions, and when decomposed it is very irritating. It is said not to keep well in solution, even in dark-colored bottles. In this connection it should be noted that silver nitrate contains 6.35 per cent of silver, occupying between protargol and argon in a middle position as to the basic salt.

The following process is given by F. Miehle for making solutions of argonin readily and rapidly: Ten parts of cold water is first introduced into a flask, and then one part of argonin. The whole is then vigorously shaken until a uniform mixture is had, when sufficient boiling water to make up the desired quantity of solution is added, the whole being frequently shaken until complete solution occurs, when the mixture is strained through a piece of gauze. The most effective solution of argonin for clinical work is one of three per cent. To prepare solutions of protargol the powder is stirred with some water, with or without the addition of a little glycerin, into a paste, and then diluted by adding the necessary quantity of cold or lukewarm water. Solutions of 0.25 to two per cent are generally employed. A saturated solution of protargol is fifty per cent.

The method of using these solutions in a case of gonorrheal ophthalmia of an infant should be described at this point, as also the whole régime of the management of the patient. Dr. Peck says that such régime requires the skilled work of a trained nurse or nurses, in conjunction with the good judgment of a physician. The best type of régime is found in a well-regulated hospital; but the same details can be carried out in a private family, under similar skilled labor and good judgment. If one eye only be affected the fellow eye should be covered securely in every part, save at the lower outer region, over the temporo-malar portion of the orbit. This little opening is left for ventilation. The least harsh covering for a newly-born infant’s eye is lint; this is cut round, slightly larger than the orbit. It is covered with a soft fluff of sterilized cotton, and this latter with gauze. Collodion is smeared around the whole edge of the pad, save at the point already noted. This protected eye may be inspected every second day. The affected eye must be handled by the nurse from behind the patient’s head. The nurse should never carry the infant in her arms. Small round layers of lint are transferred from a large square of ice every minute or two to the affected eye; and these minute changes are made for one hour without intermission, when an interval of one hour, or two or three, is given, according to the mild character of the affection. The rule is, however, to begin with continued applications of the ice-cold pledges by day and night, the patient being under the care of two nurses. No interval of application should be ordered until there is positive evidence of an abatement of secretion; this may not occur under two or three weeks, and it may result in a few days. The eyeball, lid, interspaces, and conjunctival sacs should at first be thoroughly irrigated with warm saturated solution of boric acid, the saturation point of boric acid being about four per cent. As the secretion diminishes and gets shreddy, the nurse should wipe out the discharge with cotton dipped in the same boric acid solution. Every effort should be made to keep the eye free from secretion. The protargol solution, at first five to ten per cent in strength, should be carried rather forcibly over the eyeball, and into the folds of the conjunctival sacs, by means of a large pipette; it should at first be used from four to six times a day. As soon as the secretion lessens in amount, or becomes shreddy, while its fluid part becomes thinner, the protargol solution may be brought down to two per cent, and may be used less frequently. A successful result of such treatment would be a limitation of the disease to three, possibly two, weeks.

Examinations for gonococci should be made every second day, and an eye should not be regarded as safe, or as amenable to contact with the mother, until a full week has elapsed, in which absolutely no gonococci are found under the microscope. It must not be for-
gotten that even with an apparently uninfamed eye, the sclera being white, the cornea glistening, and the lids scarcely swollen, gonococci may be present. The physician should not be too conservative as to the length of quarantine in a convalescing ophthalmia.

It is of great clinical advantage to know that protargol can be combined with many other salts, such as the sodium chlorides, alkalies, etc.; it is unaffected by cocaine, atropine, eserine, and other allied anodynes used locally in the eye, hence its field of usefulness in ophthalmia is very broad. It is not decomposed or precipitated by the albumen or alkalies present in the secretions from mucous membranes; and it may be stated that it is the only silver compound at present known which is not precipitated by dilute hydrochloric acid. Peck adds that its use in his hands in suppurations of the lachrimal sac, purulent stytes, etc., has been more frequently followed by a checking of the pus-formation than when any other agent has been employed.

Peck then quotes two cases to show the advantage to be derived from the use of protargol in the treatment of gonorrhreal ophthalmia. The results obtained show that the duration of the disease has been shortened, that gonococci have disappeared at an earlier date than usual, and that the sight of the affected eye has, to say the least, not suffered more than when other methods of treatment have been employed. In the earliest cases the protargol powder was dusted into the eye three times each day and allowed to remain fifteen minutes. This was soon changed to twice each day, but as the inflammatory reaction was marked and the patients complained of severe pain, a fifty-per-cent solution was substituted, being applied twice or thrice each day and allowed to remain in the eye three minutes. Later, a five-per-cent solution was used and allowed to remain in the eye fifteen minutes. This last solution has proved the most satisfactory.

THE USE OF DIURETIN IN DISEASES OF THE HEART AND KIDNEYS.

Sconamiglio has reported the use of this drug in thirty-one cases. In nineteen of these there was a mitro-lesion complicated by arteriosclerosis. The results of its use in these cases were admirable, but on the other hand it was not of much value in conditions of the aorta, in atrophic cirrhosis, and pleurisy. This investigator noticed that the influence of the drug persisted for a long time after its administration was stopped.—Revue de Thérapeutique Médico Chirurgical, December, 1898.

ICHTHYOL FOR PRURITUS VULVÆ IN PREGNANT WOMEN.

The Journal des Praticiens of November 26, 1898, tells us that Doisy has employed this method of treatment with great success, and that it succeeds where almost all other remedies have failed. The ointment which he uses is fifteen per cent of ichthylol in lard.

THE USE OF MYDRIATICS FOR DETERMINING THE REFRACTION OF THE EYE.

The Polyclinic of December 24, 1898, contains an editorial on this topic by Edward Jackson, in the course of which he says that a mydriatic is used for measuring refraction, not as a mydriatic, but as a cycloplegic. The important thing to be accomplished by it is to paralyze the accommodation. Only in exceptional cases will the dilatation of the pupil render skiascopy easier; or, by enlarging the circles of diffusion, add to the accuracy of measurements made with the ophtalmoscope or the test lenses.

The frequency with which the cycloplegic action of these drugs should be resorted to will probably always be a disputed point, since it is largely to be decided by the importance attached to certainty and accuracy in our measurements of refraction; and this is to some extent a matter of temperament. There always has been, and probably always will be, two classes of men, who approach their professional work from quite opposite sides. With one the question is, how can this work be done most thoroughly? With the other class it is, how can the work be done most easily, or most quickly, or to give the most striking impression of superior skill? In general medicine he who belongs in the one class hears the patient's full history, makes repeated observations, examines the urine, blood, or sputum, carries in mind the problems that the case presents, and cautiously searches for the best possible line of treatment. He of the other class asks a question or two, gives a sharp look, catches at the more obvious symptoms, and then with a knowing air writes a routine prescription, delivers a positive opinion, and drops the case out of mind. It is not strange that these two types of practitioners disagree entirely as to
the practical value of certain methods of arriving at a diagnosis.

In ophthalmology these two classes naturally disagree as to the need for mydriatics or cycloplegics in measuring refraction. Not that all the careful habitually use mydriatics, or that all careless or hasty practitioners do not—men do not separate quite that way on any question. But it being admitted that the use of a mydriatic reveals certain things that cannot be known otherwise, the one class says that these things of some importance, may be essential to a full understanding of the case, and that it is the duty of a professional adviser not to suppose or approximate, but to know with all possible certainty and exactness. The other class says that the "experienced" ophthalmic surgeon can "judge" of the glasses required "well enough" without putting the patient to the inconvenience of being "blinded" for two or three weeks with "atropine;" and that if ophthalmologists will persist in using "atropine" their patients will leave them and go to opticians who will sell them glasses without being so exacting as to their suitability.

It is interesting to observe how those who reason in this way always speak of "atropine," and the two weeks required to recover from its cycloplegic effect, as though there were no other mydriatic. Apparently they do not know that the careful observations of Norris and Risley had settled eighteen years ago that hydrosine, a more powerful and equally reliable mydriatic, entailed but one week of abstinence from near work. They write as if neither they nor their readers had ever heard of homatropine, studied by Norris, Risley, Schell, and others sixteen years ago, and in constant use ever since, which reduces the period of weakened accommodation to forty-eight hours, and which is the proper mydriatic to be used for purely diagnostic purposes in the mass of cases. To argue today against mydriatics on the assumption that atropine is the only drug of the kind worth considering, is to demonstrate ignorance of the facts of the case or a disposition to misrepresent them.

The real case against the mydriatic lies in the fact that it is generally only a means by which those who so desire (and are capable of exact observation) can make their measurements of refraction more accurate. He who does not care to be accurate, or who cannot make exact observations or estimate their value, really has no need to resort to a cycloplegic. The drug, the test lenses, and the patient cannot supply the lack of trained powers of observation or sound judgment on the part of the surgeon. If something is sought that will do this, the mydriatics do not meet the need. It is just this supposed power of mydriatics to make good the deficiencies of the surgeon that is found to be possessed equally by the latest refractometer, or the ophthalmometer.

Admitting that mydriatics may be unnecessary or unsatisfactory as a substitute for patience and skill, let us consider what they will really do. They render manifest latent hyperopia. This is something that cannot be done without a mydriatic. Latent hyperopia is not always present at any age, and its amount can never be inferred from symptoms. To know about it gives the surgeon a more complete command of the case. But though the revealing of latent hyperopia is sometimes spoken of as the only good thing the mydriatics can do, it is probably the least important of their services. Their use can prevent an overestimate of myopia and so render the exact correction of myopia both practicable and safe.

To measure anything exactly, it must be kept constant while the measurement is being made; and by securing fixity of refraction the mydriatics render possible the exact measurement of astigmatism, aberration, and anisometropia, in the measurement of which exactness is most important. It is slight inaccuracies in the measurements of these that most frequently prevent success in relieving the patient by glasses.

The measurements made with the help of mydriatics must be checked and sometimes corrected by other observations, and must be used with good judgment to be of the greatest service. But he who has them at his command has a broader, firmer basis for his opinion and advice than he who neglects such a help. And in arriving at a professional judgment, fulness and accuracy in one's acquaintance with the case are essential for the honest service of the patient, and the credit and success of his adviser.

It is certain that mydriatics are being used more and more generally in the practice of those who most carefully study errors of refraction, and their experience will in time be the guide of the profession. Guesswork and time-saving approximations belong to the sphere of the counter-prescribing optician, not to that of the careful and conscientious worker in this department of scientific medicine.
MEMBRANOUS ENTERITIS AND ITS TREATMENT.

Einhorn in an article on this subject in the Medical Record of January 28, 1899, thinks that diet plays the principal part in the treatment of membranous enteritis. While the older writers laid stress on scanty, light food, it is now generally accepted that abundant nutrition is of the greatest value. That a fluid diet is unsuitable the older authors have already been cognizant of (Da Costa, Whitehead, Siredey), and this axiom holds good in its entirety even to-day.

Recently von Noorden advised a very coarse diet, being guided by the idea that the intestinal tract should be exercised and strengthened by increased work. He recommends half a pound of bread per day containing plenty of chaff, leguminous vegetables, garden vegetables rich in cellulose, fruits with small pits and coarse skin, as currants, gooseberries, grapes—these being foods rich in undigestible material, thus forming much ballast for the bowel. Among fifteen patients subjected to this treatment by von Noorden, seven were permanently cured, seven improved, and one was unchanged.

This method has certainly much in its favor; it may be better, however, not to institute this diet abruptly, as suggested by von Noorden, but rather gradually.

Dr. Einhorn says he for his part for some years past has seen to it that his patients partook of an abundant and nutritious diet, without, however, advising substances that were too coarse. As a whole, he recommends ample food and tries to keep the patients on a mixed diet containing plenty of vegetables. In patients who have lived on a strict diet (as, for instance, milk diet or beef and hot water), he arranges the change gradually. The principle here is the same as stated by von Noorden, only not carried to such an extreme. It appears sufficient if the intestines of the patient with membranous enteritis are trained to master the foods customary in healthy persons, and the accomplishment of this object is all that is required. If we subsequently see that the organism amplly fulfils its work a few less digestible foods may then be added. It is not necessary to recommend these immediately from the start, nor are they important for the cure.

With regard to therapeutics, two phases will have to be considered—the treatment during the attack and the treatment during the interval. In severe attacks, rest in bed, warm poultices over the abdomen, a cleansing enema (of ordinary warm water, with the addition of some common table salt or essence of peppermint, one teaspoonful to a quart), and afterward the administration of codeine or opium, with or without belladonna, are of value. As long as the pains last it is necessary to give light food (small quantities frequently). In mild attacks a stay in bed may not be requisite, nor the administration of an analgesic remedy, and the diet may be the same as during the interval.

In the interval free from pains the treatment consists in the methodical application of oil enemas, as suggested by Kussmaul and Fleiner. These enemas are injected into the bowel at night, at blood temperature, the quantity being two hundred and fifty to five hundred cubic centimeters. The patient is then instructed to try to retain the oil in the bowel during the night. The patients seldom assert that they are disturbed in their sleep by these injections and have to answer Nature's call. In such an instance the quantity of oil may be reduced to one hundred and fifty or one hundred cubic centimeters. The oil should be injected every night for three weeks; then every other night for three weeks; twice weekly for four weeks; finally, once weekly for five to six months. Besides, patients must accustom themselves to a regular morning evacuation, by promptly visiting the closet every day at the same hour in the morning. Next to abundant nourishment the methodical oil cure is of the greatest importance in the treatment of this affection, and the results achieved are, according to Dr. Einhorn's experience, very satisfactory. The administration of oil injections in membranous enteritis is mentioned here and there in recent literature, especially by Ewald, but its value must be placed much higher than heretofore. The oil has not only a favorable influence upon the constipation which is always present in this malady, but at the same time also affects a diminution or a disappearance of the mucous discharges. How the oil brings this about is difficult to say. The favorable effect may perhaps be explained by the circumstance that by means of the oil the intestine is not left in an empty condition during the night, and thereby by spasmodic contraction is avoided, which must be regarded as one of the principal factors in the formation of mucus.

It is evident, according to his statements, with regard to the etiology, that enteroptosis and anomalies of the gastric functions (principally achylia) exist in a large number of
these cases. It will, therefore, be necessary to bear these points in mind and to treat the cases accordingly. The neurotic symptoms present in these cases should not be neglected in the general plan of treatment. We shall have to pay attention to a regular hygienic mode of living and ample physical exercise. In suitable cases occasionally hydrotherapeutic measures will be of value. The tonic remedies, like iron, arsenic, etc., will also prove beneficial.

**HOLOCAINE IN OPHTHALMIC SURGERY; ITS SUPERIORITY OVER COCAINE; ITS THERAPEUTIC VALUE.**

HASKET DERBY, of Boston, expresses his views as to the value of holocaine in ophthalmic surgery in the Archives of Ophthalmology, No. 1, 1899. This new local anesthetic, to which he called attention more than a year ago (Boston Medical and Surgical Journal, June 3, 1897), has not yet come into very general use, judging from the little reference made to it in the medical press, as well as the indifference manifested by so many of those who have become habituated to the employment of cocaine. Believing, as Dr. Derby does, that the latter drug is in many important respects distinctly inferior to holocaine, and having used the new agent almost exclusively for the past sixteen months, he has thought that a brief record of his own personal experience might not be without value.

In the operation for the extraction of senile cataract it is a most efficient anesthetic. While not superior to cocaine in its superficial effect, it undoubtedly causes a greater degree of insensibility of the iris. Where a simple extraction is not performed and an iridectomy has to be done, we are all familiar with the start the patients may give, as well as the pain they complain of, at this stage of the operation. Under holocaine, applied after the corneal cut has been made and the anterior chamber evacuated, it is his experience that the iris very generally allows itself to be seized with the forceps and excised without much if any suffering. This is a very great practical advantage. In connection with the operation of extraction, however, it is but fair to remark on the fact that the holocaine does not control hemorrhage as cocaine does, and that where the latter agent is not used we are liable to meet with a troublesome amount of bleeding.

For the removal of a foreign body from the cornea, holocaine is decidedly preferable to cocaine, as it neither affects the accommodation nor enlarges the pupil, thus rendering its use possible in the case of people with a tendency to increase of ocular tension. In other operations on the cornea or iris, such as that of Saemisch for ulcer serpens or iridectomy for glaucoma, it is a well known fact that a degree of inflammation that prevents the absorption of cocaine will often yield to holocaine, thus rendering the use of ether or chloroform unnecessary. Had cocaine alone been at our command, general anesthesia would have been the only resort.

In the various operations on the muscles of the eye no local anesthetic has been found to give entire satisfaction. It can only be claimed for holocaine in this connection that it is at least as efficient as cocaine, and can be used in cases where distressing constitutional symptoms have been produced by the latter.

In probing the lacrimal passage, Dr. Derby still makes a preliminary injection of cocaine, the poisonous effects of holocaine, when administered internally, rendering it unsuitable for such a purpose. For the same reason no subcutaneous injection of the drug can be made. But in the numerous cases where he has used it locally and superficially he has never seen the slightest general disturbance.

To sum up, then, the advantages of holocaine over cocaine:

1. It does not cause mydriasis, and may therefore be used without danger of bringing about increase of tension.
2. It does not affect the accommodation.
3. It brings about a greater degree of anesthesia of the iris than does cocaine.
4. In cases of severe and painful inflammation which resist cocaine, holocaine often proves efficient.
5. 'Unless swallowed or injected subcutaneously it produces no constitutional effects.
6. It has no effect on the corneal epithelium.
7. It is strongly bactericidal in its action. *Per contra*, cocaine distinctly reduces the tendency to hemorrhage, and it can be injected into the lacrimal sac, and often subcutaneously, with comparative impunity.

Such being the facts, it would certainly seem that, in the great majority of cases, holocaine should supersede cocaine as a local anesthetic in ophthalmic surgery.

A single word in regard to eucaine, which has also been proposed as a substitute for cocaine. Dr. Derby's opinion of its efficiency
is based on the following occurrence. He had operated in January of the present year on a lady of eighty for the extraction of cataract. Holocaine was used, and the operation passed off well, causing little or no pain. A month ago he undertook to remove the cataract on the second eye. His nurse, a graduate of the Infirmary Training School, had been used to cocaine, and had never seen anything else employed at an extraction. He was pleased to be able to call her attention to the advantages of holocaine, and promised her a proof of its anesthetic value on the present occasion. Greatly to his mortification, as well as astonishment, the patient complained bitterly of the pain, and asked him after the operation why it hurt so much more than it did the first time. On reaching home the mystery was explained. He had taken by mistake a bottle of a ten-per-cent solution of eucaine B, and had not noticed the substitution until his return.

But the author has found a possible use for holocaine that, as far as he is aware, has not yet been adverted to. It is based on its bactericidal properties, which were so carefully investigated by Heinz and Schlösser (Klinische Monatsblätter, Jahrg. xxxv, S. 117).

If the immediate cause of corneal ulceration is, in accordance with the present theory of suppuration, the invasion of the territory by microorganisms (Fuchs); if the ulcer separates through infection of the cornea by organisms which give rise to a purulent inflammation (Fuchs); if so severe a remedy as the actual cautery has sometimes been efficient in bringing about a cure, why may not germicidal action be induced through milder means than the application of a high degree of heat or the clumsy and round-about method of the subconjunctival injection of corrosive sublimate?

"On the development of bacteria," say Heinz and Schlösser (loc. cit.), "holocaine exerts an energetic restrictive influence. A 0.1-per-cent solution plainly retards putrefaction and fermentation; a half-per-cent solution prevents any development of bacterial germs; multiplying fission fungi are killed by a one-per-cent solution. One-per-cent holocaine is therefore an active antiseptic."

The use of holocaine in ulcers of the cornea seemed to be sufficiently indicated by the foregoing, and Dr. Derby began to employ it during the past year. His observations have been limited in extent, but thus far they have gone to convince him that holocaine has a therapeutic value previously unsuspected.

THE TREATMENT OF SCIATICA.

E. Radzikowsky (Vratch, No. 52, 1898) has obtained excellent results by the local application of muriatic acid in a series of cases of sciatica. He proceeded in the following way: The chief seat of the pains and all the other painful points along the course of the nerve and its branches are marked with a pencil, and a strong solution of muriatic acid applied. During these manipulations and for some hours afterwards the patient is kept in a horizontal position on his stomach. The effect soon showed itself in a great afflux of blood to the parts where the muriatic acid had been rubbed in, the tissues around the congestion being somewhat edematous. After the operation the patient was usually given a hot bath, which was well borne, and attended by great relief of the pains. As soon as the patient left the bath the parts were wrapped in a soft, simple dressing. Beyond the formation of vesicles at the seat of application, and in a few cases the presence of an inflammatory condition of the upper layers of the skin, no ill effects were observed; the vesicles quickly disappeared. The applications were usually repeated on the third, fourth, or fifth day, the average duration of treatment varying from four to thirty-five days. Marked diminution of the pains very frequently followed the first application, and their complete subsidence, even in cases of very old standing, ensued after four to ten applications. In some cases, however, anodynes had to be administered internally at the same time; these cases, as a rule, did not do well. By the treatment described the author claims to have cured many cases of sciatica which had resisted all other treatment. In such cases, where the complaints could be traced to a rheumatic, gouty, or inflammatory origin, the treatment was especially attended by favorable results. Mild cases were treated as out-patients; more severe ones, however, had to be admitted to the hospital.—British Medical Journal, Feb. 11, 1899.

DANGEROUS INCOMPATIBLES.

An important case, but with a sad sequel, has been reported to us by a correspondent in Johannesburg. The death of a young woman was caused by the administration of a medicine containing liquor strychniæ in conjunction with liquor arsenicalis. We do not know the precise circumstances of the case, but it should be instrumental in
drawing serious attention to the question as to whether such a combination should be given together in a mixture in a bottle. Of course the alkali of the liquor arsenicalis precipitates the strychnine in the form of the pure alkaloid, and the residue, which may amount to an excessively poisonous dose, may be taken in the last dose in the bottle. We have no hesitation in saying that such a mixture should never be dispensed, although we find it stated in books on dispensing that “liquor strychninæ and liquor arsenicalis are sometimes prescribed together. In this form the alkali of the latter precipitates the strychnine, so that a shake-the-bottle label must be used.” The risk, we consider, is too great to countenance such a mixture being dispensed. The alkaline solution of arsenic should be kept separate from the strychnine, and the two should be administered separately in equal quantities. The discretion of the public is too variable a factor to be relied upon to seriously observe the notice to shake the bottle in the case of mixtures likely to contain an extremely poisonous sediment. We may add that the use of the liquor arsenii hydrochloridi would obviate all risk of strychnine poisoning from precipitation.—Editorial note in London *Lancet*, Feb. 11, 1899.

*PARALDEHYDE IN ASTHMA.*

Dr. Macgregor says in the *Lancet* of February 11, 1899, that as far as he has been able to find out, Dr. Mackie, of Elgin, was the first to suggest the use of, and to use, paraldehyde for the relief of asthma. “The fact that paraldehyde is a sedative largely eliminated by the breath” led him to try its effect in the spasm of idiopathic asthma. He administered it in a number of cases with uniformly successful results, and found that it speedily relieved the spasm and induced sleep. Dr. Macgregor’s attention was drawn anew to this a few months ago, and since then he has given the drug in a fairly large number of cases of idiopathic asthma and other forms of spasmodic dyspnea, and his experience confirms that of Mackie. Dr. Macgregor says that no drug in his hands has given such satisfactory results. In the treatment of hospital out-patients suffering from asthma morphone hypodermically is out of the question, and it is not usually advisa-

**THE TREATMENT OF HEADACHE.**

Dr. Joseph Collins writes an article on this practical subject in the *Medical News* of February 18, 1899. He says that those headaches accompanying the infectious diseases do not call for any particular treatment aside from the measures taken to combat the infectious processes, while the treatment of headache due to the ingestion of vegetable or mineral poisons resolves itself into the very simple matter of preventing the further inhibition of the poison, be it tea, alcohol, tobacco, or poisonous substances administered therapeutically or encountered in occupations, and the elimination of any of the poison remaining in the system from the body. After that the headache disappears on the restoration of general, including neural, nutrition. To bring about this restitution of nutrition general tonic treatment is required. And meanwhile, the headache may be relieved temporarily by the administration of some of the prescriptions possessing analgesic properties. A formula that Dr. Collins often uses as a general tonic and stimulant in headaches following the infectious and exogenous intoxications is as follows:

Opii pulv., gr. ss;  
Zinci phosphid., gr. ss.  
M. Ft. pil. No. 20. Sig.: One pill three times a day.

Dr. Collins says that the tonic effect which one gets from this small quantity of opium is nothing less than remarkable. All the infections and intoxications, without exception, produce a more or less profound condition of general anemia, and this anemia must be reckoned with in estimating the nature and determining the treatment of the headache. Early in the treatment of such headaches some such searching tonic as the following should be administered:
He is especially apt to give this mixture to children who complain of headaches following the infectious diseases, while for adults the mixture ferri ammonii acetatis is substituted for the citrate salt.

In the treatment of headaches resulting from the absorption into the system of some endogenous poison, such as that of diabetes, uremia, and the autointoxications and infections, the general measures to be adopted do not differ materially than those already spoken of. The headache is combated when the formation of the poison and its absorption into the system is interfered with. In this way diabetic headaches are treated by diet and by the utilization of remedies against the anemia and oligocytaphemia, while uremic headache is combated by measures that prevent the formation of urea, and by those that facilitate its excretion. In uremic headaches accompanying chronic interstitial nephritis of slow progression, Collins uses the following prescription as a diluent and diuretic with good effect:

- Potassii citratis, f 3 ij;
- Tinct. hyoscyami, f 3 ij;
- Spt. etheris nitrosi, f 3 ij;
- Inf. scoparise, f 3 vj.

M. Sig.: Tablespoonful in water three times a day.

If it is necessary to increase vascular tension, infusion of digitalis may be added to this mixture.

Headaches arising from such intoxication as that of ammoniemia require only local treatment of the cystitis and the institution of measures to combat the anemia.

Headaches arising from autointoxications, the original source of the disease being stomachic and intestinal catarrh, functional perversity of the glands supplying the digestive juices, or through the activity of non-pathogenic bacteria, taken in from outside, form an important class, and one that is happily rather amenable to treatment. It must suffice in this connection to say that after the general measures for the regulation of the alimentary tract and its associated functional dependencies, such as the overcoming of constipation, the adoption of suitable diet in catarrhal conditions, the stimulation of the liver to the production of a suitable kind and amount of bile, the exhibition of substances that contribute to the restoration of the pancreas and spleen, the treatment consists in the administration of substances that correct the apparent troubles of digestion and of substances that quell the headache. A favorite prescription of Dr. Collins' for headache associated with flatulence and pyrosis is the following:

- Sodii bicarb.,
- Bismuthi subgallate,
- Pulv. acaci, each 3 j;
- Liq. ammonii anisi, f 3 iii;
- Aqua dest., ad f 3 viii.

Sig.: Two teaspoonfuls before meals, repeated in three hours if necessary.

In headaches associated with atonic dyspepsia, but without any considerable flatulence, Collins makes use of the following pills, and especially in the headaches occurring in women:

- Ferri sulphatis,
- Quininae sulphatis, &s grs. xv;
- Sodii arsenitis, gr. ss;
- Pulv. rhei,
- Pulv. zingiberis, &s grs. x.

M. Ft. pil. No. 12. Sig.: One pill three times a day after meals.

The treatment of headaches due to disease of the circulatory system requires considerable discussion, not so much because of their frequency as because of the fact that if they are properly interpreted they yield readily to treatment. The headaches that accompany organic diseases of the heart, whether they be associated with excess or deficiency of propulsive power, naturally require treatment directed to that organ, as does any pulmonary condition which interferes with the return cerebral circulation. Headaches occurring with functional disturbances of the heart are oftentimes very amenable to therapeutic measures, not drugs. For instance, a heart that is working violently as the result of great physical effort or excitation of mind or body may be so quieted by the application of a simple cold-water compress to the cardiac region that the accompanying frontal throbbing headache disappears promptly, and the efficaciousness of stimulating foot-baths and hot sitz baths in combating a headache of increased vascular tension within the skull is very well known. It is rarely necessary to administer the more powerful cardiovascular depressants in cases of this kind, the required equalizing of the circulation being obtained by hydric procedures and the administration of a few doses of the bromides. When headache is an accompaniment of a sluggish circulation, there being no deficiency in the amount of the blood and no alteration of its constitution, the diffusible stimulants, caf-
feine and strychnine, may be relied upon to bring about its prompt relief. Cannabis indica is a drug that he frequently uses with good effect in this form of headache. The method of prescribing it is in the following pill:

\[ \text{B} \text{ Ext. cannabis indicæ, gr. } \frac{1}{2} \text{ to ss;} \]
\[ \text{Ext. gentianæ, q. s.} \]
\[ \text{M. Ft. pil.} \]

Headaches that are dependent upon a general anemia are oftentimes extremely resistant to treatment, and although temporary improvement usually follows tonic and stimulating treatment, the anemia must be fought unwaveringly for a long time to effect a complete cure, and to stay the recurrence of the headache. These headaches are usually accompanied by a very slight sluggish condition of the digestive tract, to combat which he has used with very good results the following combination of tonics and laxatives in the shape of a dinner pill:

\[ \text{B Quinine sulph.,} \]
\[ \text{Ext. aloes aq., } \frac{1}{2} \text{ grs. xii;} \]
\[ \text{Pulv. capsici,} \]
\[ \text{Pulv. ipecac, } \frac{1}{2} \text{ grs. vj;} \]
\[ \text{Glycerini, q. s.} \]
\[ \text{M. Ft. pil. No. 12. Sig.: One pill at midday.} \]

Or, if associated with considerable vital depression, he uses the following pill instead, giving at the same time some absorbable form of iron:

\[ \text{B Ext. nucis vomicae, gr. ss;} \]
\[ \text{Pil. rhei comp., gr. iii;} \]
\[ \text{Pulv. capsici, gr. q.} \]
\[ \text{M. Ft. pil. Sig.: One pill at midday.} \]

Naturally it is very often necessary to give at the same time, for its immediate effect, some analgesic or a combination of these with a stimulant, such as caffeine, and such a prescription as one given above, containing caffeine, phenacetine, and salol, usually meets the requirements.

\[ \text{CEREBRAL INJECTIONS OF ANTITETANIC SERUM.} \]

The good results obtained in the treatment of diptheria by means of serum-therapy have encouraged similar and persistent attempts in the treatment of nearly all the infectious diseases. Tetanus, one of the most fatal of the entire group, has not been omitted in these investigations. Not content with the comparative failure which attended subcutaneous injections, the antitoxin was tried intravenously, but still the results were by no means promising. The researches of Roux and Borrel, at the Pasteur Institute, Paris, led them to these conclusions: "The tetanus antitoxin, when injected into animals, remains in the blood, whereas the toxin (previously absorbed) is extracted from it and 'fixed' by the nerve cells. The antidote does not come in contact with the poison, and the two substances, though so near each other, fail to meet. The serum is efficacious against the toxin which is placed under the skin because the greater part of it enters the blood, but it proves powerless against the poison that has already reached the nervous elements" (Dr. Rambaud, in the New York Medical Journal, Dec. 17, 1898).

We now readily understand the whole difficulty. The subcutaneous and intravenous injections were productive of so little good merely because they did not reach the seat of trouble save in the minutest amount. As a rule, subcutaneous injections have not been resorted to in cases of tetanus until the disease has been well advanced—that is to say, until a great part of the toxin manufactured by the tetanus bacilli has been "fixed" in the nerve cells. In order to reach these nerve units, the toxin must travel the route of the circulation, so that when any good has been accomplished by the subcutaneous and intravenous injections, it has been through the neutralizing effect upon these toxins within the circulation, but little if any effect being produced upon the toxins "resting" in and exerting their deleterious action upon the nerve cells.

If this theory be true, the only hope of success with subcutaneous or intravenous injections lies in their early application, thus keeping the blood in a diluted antitoxic state until all danger of absorption of toxins from the original site of infection is past. If, however, the opportunity for thus combating the toxin while in the blood-current be neglected, the only hope of reaching it efficiently must be through some method that brings the antitoxin face to face with the toxin in the cells of the cerebrum. Suiting the action to this logical conclusion, the bold experiment was undertaken of injecting tetanus antitoxin directly into the brain substance, and with gratifying results. Rambaud has collected reports of twelve cases in which the intracerebral method of injecting tetanus antitoxin was followed, and the results recorded have been far better than those of any other plan of treatment thus far produced—five recoveries. Of these twelve cases, three of the patients were treated in this country, with a
mortality of two, but the histories given of the latter demonstrate that neither was a fair example on which to rest the value of the treatment, as one was dying at the time of the injection, while the other, though apparently recovering from the tetanus, succumbed to renal disease, a concomitant of a general septic condition into which the patient had fallen. In the patient who recovered, reported by Church, the tetanus developed twelve days after the primary injury, a large lacerated wound of the leg produced by glass broken during a severe fall. Six days after onset—that is to say, when the poison had become fixed in the nerve cells—antitetanic serum was used subcutaneously, but with little benefit. Improvement being but temporary, it was decided the next day to make an injection of the serum into the frontal lobe of the brain. After trephining the skull, which was done under antiseptic precautions, sixty minims of the serum was slowly deposited to a depth of more than two inches, the entire injection taking longer than ten minutes. The subsequent history was comparatively uneventful, the patient making a good recovery.

If we accept the observations of Roux and Borrel, the neutralizing of the poison stored in the brain tissue by injection of an antitoxin into this tissue is also to be accepted. Indeed, the good results obtained by means of this method after subcutaneous and intravenous injections have failed would go far to show that these observers are correct. It would seem, also, that the right thing to do in all cases of tetanus, regardless of their mildness or the reverse (all cases of acute tetanus must be considered grave at any stage), to proceed at once to the intracerebral injection, at the same time not neglecting to neutralize the poison in the blood by subcutaneous or intravenous treatment, or both.—Editorial in Medical News, Feb. 18, 1899.

THE TREATMENT OF PATIENTS SUFFERING FROM PULMONARY TUBERCULOSIS WHO CANNOT GO AWAY FROM HOME.

The Medical News of February 25, 1899, has in it an article by Dr. Rochester upon this subject. He says as far as his experience goes nuclein, administered hypodermically, is the best remedial agency in early cases. He has several cases of apparent cure from this treatment. Among remedies administered by the mouth, creosote, or some of its derivatives, still stands at the head of the list. In the administration of creosote it is important in the first place to secure a pure article, to administer it regularly, always after food, to increase the dose gradually but regularly, carefully watching the urine, as well as looking for gastric disturbance. He has given as much as two cubic centimeters at a dose three times a day for three months in this way. The gradual reduction of the dose is as important as the gradual increase in its size, the sudden stopping of the large dose sometimes producing very unpleasant results. The carbonate of creosote has not been of any greater value than the pure creosote, nor has it been better borne by the stomach. The same may be said of the carbonate of guaiacol as compared with guaiacol. In some cases guaiacol can be taken where creosote cannot. When there is a great deal of pus in the sputum tertene combined with the guaiacol is often of value. Balsam of copaiba is also often of great use under similar circumstances. It can be easily administered in emulsion with mucilage of acacia and syrup of tolu. In cases in which there is marked intestinal fermentation or gastric intolerance of pure guaiacol, the benzoate of guaiacol is often tolerated and acts very well. It can be given in doses, gradually increased, of from 0.25 to one gramme, three times daily, in capsules. In all patients in whom it does not produce gastric or intestinal disturbance cod-liver oil is still our sheet-anchor in the medicinal treatment of phthisis; nothing has yet been found which can take its place. The pure oil can be taken by some individuals, but not many. An emulsion can generally be made which will be tolerated by the stomach. After taking cod-liver oil for a while, whether pure or in emulsion, the individual generally becomes accustomed to it to such a degree as actually, in many cases, to like it. In these days of proprietary medicines and made-up emulsions, which are said to be strictly ethical, and are said to contain thus and so, whose working formulæ, however, are not published, many physicians are losing the art of prescribing; but really a freshly made emulsion, put up by a competent pharmacist, is much to be preferred to all others.

Special symptoms in some cases call for special treatment. Rochester refers briefly to some of these. Pain in the chest is not infrequently a troublesome matter. Its cause should be searched out. If due to pleurisy it should be treated by strapping or dry-cupping the chest; if it is a neuralgia it is
best relieved by aconite ointment locally, general treatment, and building up of the general resisting power. Sometimes the local use of iodine in ointment or tincture seems to be of avail, but in such cases it seems to him that time is as much a factor as the iodine. Cough is a necessary concomitant of pulmonary tuberculosis, and should not be too rashly interfered with. A troublesome, irritating cough with little or no expectoration is generally due to pleurisy or some disturbance of the upper air-passages, and treatment should be directed accordingly. Cough is best treated by inhalations, such as have been suggested, or by the administration of hydrocyanic acid and chloroform water. Cough is frequently a matter of habit and can be prevented by mental discipline. The administration of cough mixtures containing stimulating expectorants and opium should be avoided as far as possible. It is very seldom that the stimulating expectorant has any place in the treatment of phthisis, and opium and its derivatives are absolutely out of place, except in advanced cases beyond recovery, in which nothing can take their place. To a patient in advanced phthisis opium is truly the great and good gift of God to man. Hemoptysis is best treated by rest in bed and the administration of morphine and atropine hypodermically.

The fever of tuberculosis is best treated by the sponging and general plan of treatment already suggested. The use of antipyretics is to be deprecated. Sweats are best combated by general treatment and the baths and induced sweats referred to, but they sometimes call for special treatment. Dr. Rochester says in his hands nothing can equal atropine in the relief of this distressing symptom.

Of the gastric symptoms requiring special treatment vomiting is the most distressing. Sometimes it is absolutely necessary to put the patient to bed in such cases. Careful investigation of the stomach with the tube is sometimes of value. In severe cases of vomiting in phthisis, however, whether induced by cough or not, large doses of cerium oxalate, one gramme at a time, are of especial value. Of the intestinal symptoms diarrhea is the most serious. If the general treatment as outlined does not relieve this condition, benzoate of guaiacol is our most useful drug. In the distressing diarrhea of advanced phthisis, however, nothing can take the place of the lead and opium pill.

In closing his remarks Rochester makes a plea for the careful study of individual cases and the use of treatment especially adapted to each particular patient, and the avoidance of routine treatment of cases of pulmonary tuberculosis.

ARREST OF HICCough BY DEPRESSING THE TONGUE.

The Maryland Medical Journal of February 25, 1899, contains an article by Kolipinski with this title.

Hiccough, like vomiting, is often so severe and persistent that credit or discredit is bestowed on a physician in a case dependent on his ability to stop it. The method described below is offered that further trial may demonstrate whether it possesses sufficient value to be included in the list of means at present in our possession for checking this troublesome and often distressing symptom, common alike to a number of curable and fatal diseases.

C. H., fifty-nine years of age, a shoemaker of vigorous constitution, but somewhat impaired by the long-continued use of alcoholic intoxicants, had suffered from chronic gastritis. December 14, 1898, he was able to go to work, but complained of headache, vomiting, and oppression of the chest. A persistent hiccough began. That night he could obtain but little sleep. The next day he was not able to eat his meals. The hiccoughs growing worse, he took some remedies of an apothecary and also sent for a physician. He made an attempt at his daily work, but soon gave it up and returned home. He slept but little, the hiccough being so violent that his bed shook, and he passed the night mostly sitting up. Various home remedies were next tried, but without relief.

On the 16th patient found himself too weak to work, and remained in bed, passing another sleepless night. December 17, condition the same; he went to his shop, but had to return home. He had no sleep at night, but was "up and down." His throat felt swollen and full, so that he suffered much from dread of death by suffocation.

December 18 the condition was the same. Dr. Kolipinski saw the patient that night. He was much alarmed, and declared the hiccough was killing him. Dr. Kolipinski tried to reassure the patient, and directed him to breathe slowly, lying supine, and to extend his arms above his head. The hiccoughs caused a tremor of his whole body.

Patient complained of the fulness in his
throat, a condition which he thought the result of the hiccough. Dr. Kolipinski directed him to sit up, and with a large spoon-handle, pressing the tongue down and back with steady force, was enabled to inspect the fauces. He found the soft palate congested and the uvula thickened and elongated. The hiccough recurred twice, and each time could be noted the elevation of the soft palate and uvula in the act. He continued the firm pressure on the tongue with the hope of further noting the action of the palate muscles, when to his surprise and to the patient's great astonishment and joy the hiccough ceased. Under a dose of morphine and chloral he passed a comfortable night.

An hour after Dr. Kolipinski's departure the hiccough returned, but the patient with great zeal and confidence placed himself in front of a mirror, passed the spoon-handle to the back of the tongue, and with both hands depressed and steadied it. The hiccough at once ceased. In the morning, on awakening, the hiccough returned, but stopped spontaneously on his getting up and dressing. Two days later it reappeared, but was promptly arrested by the patient himself in the manner described. The time required in each instance to accomplish the desired result was one minute or less.

BLINDNESS FOLLOWING THE INTOXICATING USE OF JAMAICA GINGER; REPORT OF SIX CASES.

HIRAM WOODS, JR., reports these cases in the Ophthalmic Record for January, 1899. He thinks that in studying his cases with reference to the lesion present and its cause, Thomson's case can be advantageously added. They may be regarded with reference to their history and previous condition. All of the seven, except Chisolm's patient, were periodical drinkers. He was addicted to sprees in addition to the daily moderate use of stimulants. In only two (Cases 2 and 6) was tobacco used immoderately. In but one was there systemic trouble (albuminuria with casts) to which blindness could be attributed even indirectly. The manner of its appearance was entirely unlike the usual ocular manifestations of chronic Bright's disease. In only one (Chisolm's) was there reason to suspect a previous toxic amblyopia. It seems safe to conclude that in none of the seven were there conditions apt to produce such effects as followed the ingestion of the ginger.

The cases may be further studied from the standpoint of intoxicants employed. Jamaica ginger only was used in Thomson's and Case 1. Case 6 drank ginger and other substitutes for liquor. A half-ounce of alcohol was the sole intoxicant besides ginger used by Case 3. Cases 4 and 5 had drunk liquor five and seven days respectively before the onset of eye symptoms; had been over its intoxicating effects several days, and had imbibed freely of ginger only and of ginger and other adulterated drinks just before blindness came. Case 2 drank whiskey and ginger indiscriminately to the last. It is seen that ginger is the only intoxicant used by all; that, barring the half-ounce of alcohol in Case 5 (which, probably, had little influence) and the whiskey used by Chisolm's patient, ginger and other adulterated alcoholic drinks were the only agents used in immediate connection with the appearance of blindness. A third point of interest is the mode of onset. Save in one case, the first evidences of trouble were gastric pain, nausea, headache, twelve to forty-eight hours after ingestion of ginger. Then came dimness of vision, rapidly followed by total blindness.

Regarding the nature of the lesion, Thomson thinks it is an acute retrobulbar neuritis. Attributing, as he does, the whole picture to alcohol, he blames the dimness of vision on the first day to an alcoholic "central scotoma, negative in character, for color, not form." He attributes the increasing blindness to rapidly increasing pressure on axis cylinders, improvement after several days to absorption of the effusion, the macular bundle remaining more seriously affected on account of its deep situation in the nerve, and consequent exposure to greater pressure. The permanent central blindness he attributes to consecutive atrophy of the macular fibers. In two of Dr. Woods' cases, both of which went on to complete atrophy, the neuritis was far enough forward to show as a papilitis.

THE TREATMENT OF PNEUMONIA.

We published about three years ago a series of papers upon the treatment of pneumonia adopted in various children's hospitals of this country. We have also published a long discussion upon the treatment of the same disease in hospital and private practice. Although opinions differ more widely upon therapeutics than upon any other subject in
medicine, the essential methods advocated in these various papers were more nearly uniform than might have been expected. It is evident that the same general principles underlie the treatment adopted by most men of large experience. All agree in the fact that in infants pneumonia usually reaches a fatal termination by exhausting the vital power, and that every means, therefore, should be utilized to conserve that power. The digestion is easily deranged, and the appetite impaired. Any drug, therefore, be it ever so efficacious in relieving cough or other symptoms, if it disturbs the digestion or destroys the appetite, may result in more harm than good. As there is doubt regarding the power of any drug over the disease, it is not strange that drugs should be used but little by the men of largest experience. It is true that certain medicines are of great value in combating certain complications, but it is yet to be proved that any medical agent possesses a controlling influence over the disease per se.

There can be no doubt that cases are sometimes lost through overzealousness. Through the desire to leave no means untired, medicines and doses are multiplied, local applications are vigorously employed, the temperature is taken with unnecessary frequency, and the little patient is kept in a continual state of disturbance and excitement and is literally worn out for the lack of necessary rest and sleep.

While there is no specific treatment for pneumonia, there can be no doubt that many lives are saved by proper management. Careful feeding and hygienic management, counter-irritation and inhalations, and judicious stimulation, will save more children from death by pneumonia than can be saved by the filling of weak and irritable stomachs with irritating or nauseating drugs.

In a recent discussion upon the treatment of pneumonia in children Dr. L. Emmett Holt thus summarized his views: (1) No depleting measures are ever admissible; (2) hygienic treatment is indicated, such as fresh air, proper feeding, and good nursing; (3) no unnecessary medication is permissible; (4) many annoying symptoms may be relieved by local measures; (5) the administration of stimulants should be determined solely by the condition of the pulse; (6) high temperature is much more safely and effectively controlled by cold than by drugs; (7) greater caution is necessary in the use of powerful drugs than is generally observed; and (8) rest is quite as important as in any other serious disease.—Archives of Pediatrics, February, 1899.

THE CONDUCT OF THE HEART IN THE FACE OF DIFFICULTIES.

The Medical Press and Circular of January 18, 1899, contains an article on this topic by Sir William Broadbent. In discussing this important theme he first draws attention to the difficulties arising out of flatulent distention of the stomach or colon or intestinal canal, which will generally require some attention, since they are the cause of most of the functional derangements to which the heart is subject, and give rise to the heart complaints which occasion in the aggregate perhaps more suffering than does actual heart disease. The heart often tolerates a considerable degree of upward pressure of the diaphragm, and it is not uncommon to meet with stomach resonance as high as the fifth space, and to find the apex beat displaced upwards and outwards to the fourth space and outside the nipple line without conspicuous symptoms. But the heart behaves very differently in different subjects in the presence of flatulent distention of the stomach. It partakes of the general constitutional condition of the individual. In the strong, therefore, it is vigorous; in the weak it cannot be anything but weak. Then the heart has very special relations with the nervous system; it reflects every emotion, beats high with courage, is palsied by fear, throbs rapidly and violently with excitement, acts feebly under nervous depression. But it is not only through the cerebrospinal system that the heart is influenced; it is in immediate relation with the vasomotor nervous apparatus, and in a scarcely less degree with the sympathetic system generally. Normally afferent impulses are brought from the viscera to the central nervous system, by means of which their blood-supply is regulated, and their functional activity governed. These afferent impulses when perverted by functional derangement or disease may become serious disturbing influences. But the nervous system in a large and increasing proportion of people is unduly sensitive and excessively mobile, and the reactions to influences of every kind are exaggerated. A little emotional excitement gives rise to palpitation; a piece of bad news or the bang of a door seems to stop the heart altogether. There is in such subjects no form or degree of
cardiac disturbance which may not be caused by indigestion, scarcely any symptom of cardiac disease which may not be simulated. Add a touch of hysteria on the lookout for symptoms and for some one to give ear to the relation of the unparalleled agonies of the sufferer, and the difficulties of the heart, and it may be added of dealing with them, are complete.

It is of course of the greatest importance that we should be able to distinguish these functional affections of the heart from troubles due to organic disease, and this is especially the case where there is severe pain in the cardiac region. The absence of physical signs of valvular or structural change will be a help, but murmurs may be present at one or more of the orifices during palpitation when there is no valvular affection, and there may be actual mitral or tricuspid incompetence when all the symptoms are really of neurotic or dyspeptic origin.

Angina pectoris is one of the cardiac affections which may be closely simulated by the effects of dilatation or functional derangement of the stomach. The first question to be put in a case of cardiac pain of anginoid character is as to the circumstances under which it comes on—whether as an effect of exertion or during repose. The earlier attacks of true angina are practically always provoked by exertion, while spurious angina is specially liable to come on during repose. It is true that angina when established may come on in the night, or may be induced by the act of undressing and the contact of cold sheets, but there will be a history of attacks during exertion. Pain and a sense of suffocation may also be brought on by the pressure of the abdominal viscera reenforcing that of a distended stomach on lying down whether the heart is diseased or sound, and a weak heart may actually be brought to a standstill in this way. Speaking generally angina pectoris in a woman is always spurious, and the more minute and protracted and eloquent the description of the pain the more certain may one be of the conclusion. Again, when palpitation or irregular action of the heart, or intermission of the pulse, or pain in the cardiac region, or a sense of oppression, follows certain meals at a given interval, or comes on at a certain hour during the night, there need be little hesitation in attributing the disturbance, whatever it may be, to indigestion in one or other of its forms. Nightmare from indigestion is not a bad imitation of true angina. So also if any cardiac symptom or pain can be walked off, it may usually be set down as functional, and due to some outside disturbing influence or to nervous irritability. The same may generally be said of intermission of the pulse, of which the patient is conscious, and, though with less confidence, of irregularity of the heart's action—if the patient feels it the irregularity is usually temporary, and not the effect of organic disease.

In these functional affections it is not the heart which is to blame; it is more sinned against than sinning, and if its difficulties are removed there will be nothing to find fault with in its conduct. The difficulties are, as has been said, the state of the nervous system, on the one hand, and of the digestion on the other, and according as the neurotic or the dyspeptic element predominates will be the treatment required. No details need be entered into, but one observation may be made. Patients suffering from those functional derangements of the heart usually make them a pretext for avoiding exercise and fresh air and often for taking stimulants or drugs, whereas exercise and fresh air are what he or she most needs. The best way to prevent the expenditure of superfluous energy on the part of the heart in the form of palpitation is to give it a fair amount of legitimate physiological work to do; and to relieve one attack of palpitation or faintness by alcohol is to invite another, while the terrible danger of drifting into alcoholism is incurred.

One of the most common difficulties with which the heart has to contend is high arterial tension, or rather the obstruction to the onward movement of the blood in the capillaries and arterioles, which is the cause of the high pressure in the arteries. While dyspeptic troubles and other reflex sources of irritation give rise merely to functional affections of the heart, high arterial tension when persistent is a frequent cause of actual disease. The resistance in the peripheral circulation has to be overcome, and the heart rises to the occasion. It puts forth the increased energy required, and in doing so becomes hypertrophied. Hypertrophy is not disease, though sometimes the heaving impulse and powerful throb of the apex are complained of by the patient and looked upon with suspicion by the medical man; but the development of additional muscular fiber is accompanied by the development of increased connective tissue, and when in the decline of life the nutrition of the more highly organized structures is no longer vigorous, the fibroid element may gradually predominate over the
muscular, or fatty degeneration may take place.

But the valves may suffer before the muscular walls. Where greater force is required to propel the blood into the aorta there is greater strain upon the mitral valves during systole, and a more violent recoil upon the semilunar aortic valves during diastole. This gives rise to chronic inflammation of the valves, with thickening and contraction, and, in the long run, insufficiency.

Dr. Broadbent says it is necessary to mention high arterial tension on account of its frequency and importance as a source of cardiac difficulty, but he has dealt with it so often and so recently that he will forbear from further dwelling upon it on the present occasion, only remarking that the recognition of unduly high pressure in the arteries affords one of the most valuable indications for treatment in a great variety of conditions. He says he is afraid it often escapes recognition, and sometimes digitalis is given for the relief of the cardiac discomfort which may attend it. This is like knocking the head against a stone wall, for digitalis not only acts on the heart but tightens up the vessels, and so increases the obstruction, which is already too great.

Coming now to the serious difficulties to which the heart is exposed by reason of damage to one or other of its valves, we discover, say, a systolic murmur at the apex or at the right second intercostal space, indicative of leakage of the mitral valve or of interference with the blood-current at the aortic orifice. What are we to do? Frighten the patient out of his life or out of his peace of mind? Condemn him at once to live on one floor, and forbid him exercise and excitement and all that makes life tolerable, and give digitalis? Certainly not. Or shall we ignore the murmur on the chance that it may not be serious, which is not an uncommon proceeding when a medical man has predicted sudden death once or twice, and found the patient to go on living for ten or twenty years? This would be equally unreasonable.

The first thing to be done is to ascertain what the murmur really means—whether, when it is mitral, there is much or little regurgitation, or, if aortic, whether it signifies mere roughness or actual constriction. Numerous considerations enter into the determination of these questions, of which we need specify only those arising out of the conduct of the heart. If, in the case of mitral incompetence, there is any considerable reflux into the left auricle, the first effect will be damming back of the blood entering it by the pulmonary veins, and the obstruction thus created will make itself felt in the pulmonary artery, raising the blood-pressure within it. There is no branch of the pulmonary artery on which we can place our finger or a sphygmograph but the high pressure is at once accused by accentuation of the pulmonic second sound. If the circulation is to be maintained under these circumstances something must be done to overcome the obstruction in the pulmonary circulation and neutralize the mitral reflux. This can only be by increase in the capacity and strength of the right ventricle. The right ventricle accordingly becomes dilated and hypertrophied, and the dilatation and hypertrophy, which we call compensatory, become for us the measure of the regurgitation. This is the conduct of the heart in the face of this particular difficulty, and we learn from the amount of compensatory change required to neutralize the effects of the valvular lesion whether the lesion is severe or slight; our conduct then will be guided by the degree of efficiency of the compensation. When there is no appreciable hypertrophy of the right ventricle, or marked accentuation of the pulmonic second sound, and the patient has no heart symptoms, the murmur means nothing, and there is no need to interfere in any way with the patient's mode of life even if this includes hunting, or climbing, or swimming, or cricket. Dr. Broadbent says he should draw the line at football or training for races of any kind.

If with marked hypertrophy and dilatation there is still no breathlessness on ordinary exertion or other circulatory symptoms the regurgitation is considerable, but it is neutralized by the compensatory changes. We are not called upon to do anything, but the patient must be warned that the compensation may easily be broken down, and that a single imprudent act of violent or sustained exertion may do irreparable injury.

Cardiac symptoms, such as breathlessness on slight provocation, show that the compensation is inadequate, and it is only by great carelessness that the serious effects of the valvular lesion can be put off. Let us suppose that we have the heart landed in extreme difficulties from incompetence of the mitral valves, the liver enlarged till its lower border crosses the abdomen at the level of the umbilicus, the veins of the neck distended and
pulsating, the face and lips livid, the lungs congested, the legs dropsical, the urine scanty, turbid, and albuminous, the patient gasping for breath and unable to lie down. It is in mitral incompetence that digitalis and such like remedies find their opportunity. But first the right side of the heart must be relieved from the overdistention which is paralyzing its efforts. Unless this is done the digitalis may simply help the straining ventricle in the work of self-destruction. The nearest approach to a modern therapeutic miracle is seen on bleeding in a good case of this kind. Dr. Broadbent says by a good case he means one in which the onset of the severe symptoms has been sudden under the influence of some adequate exciting cause, such as overexertion or chill, in a fairly robust subject with a powerful right ventricle. The venesection must be followed up by a good calomel purge, two or three grains of calomel, with, say, five of colocynt and hyoscyamus, and perhaps a dose of a saline purgative. Bleeding, however, is too heroic a method for these degenerate days, and it is not always easy to say whether it is really demanded. A good alternative is six, eight, or a dozen leeches over the enlarged liver, followed up of course by the calomel purge. In less severe cases we may content ourselves with the mercurial aperient.

The right heart having been relieved, digitalis may be given with excellent effect in different combinations, according to the condition, with nux vomica and ammonia and perhaps ether, or with acetate of iron and potash. If the edema is considerable it should be drained off by Southey's tubes, and any pleural effusion should be withdrawn by aspiration at an early stage.

Mitral incompetence will serve as an illustration of the difficulties imposed upon the heart by disease of the valves. They differ in the different valvular affections, and the heart responds in a special way for each one. The principle which he wishes to emphasize is that when the heart is in difficulties, we can generally do more for the relief of the patient indirectly by removing the difficulties than directly by aiding it to overcome them. This is the case whether the disturbing influence is external to the heart, as, for example, a dilated stomach or distended colon, or resistance in the peripheral circulation, or is a secondary effect of disease of the heart itself, as illustrated by overdistention of the right ventricle. Or, to take another instance, if the heart is in a state of fatty degeneration it is useless to give cardiac tonics; but its work can be diminished by keeping down the arterial tension, and a fatal issue may be for a time averted by preventing distention or dilatation of the stomach. Such illustrations might be multiplied indefinitely.

When, therefore, we are considering the treatment of cardiac disease or disturbance, the first question to engage the attention is how we can relieve the laboring or harassed heart by the removal of some condition which is causing or aggravating the difficulties with which it is contending. In doing this we often put an end to the symptoms which have given rise to suffering and anxiety, and in all cases we make the action of digitalis or other cardiac tonics more efficacious.

---

**THE PRESENT STATUS OF THE ANTISTREPTOCOCCIC SERUM.**

In the *Boston Medical and Surgical Journal* of February 2, 1899, Cotton gives an interesting study of this subject. As he well says, with so large a number of clinical cases on record it would seem possible to draw some conclusions, but unfortunately many of the cases are not so presented as to be of any particular value, and such conclusions as can be drawn must be mainly negative. Before drawing conclusions as to the value of any remedy one must either see its effect in disease ordinarily running a definite typical course, or there must be a decided drop in a heavy mortality, or else an opportunity to compare long series of cases with and without the given treatment under otherwise like surroundings. In the present case the first two conditions are in no way fulfilled, the third only apparently; apart from Marmorek's own cases, a large proportion of the cases of all sorts have been reported in ones or twos by different observers. This is at best a poor way of getting statistics, and here especially unfortunate, since these are just the sort of cases where the personal equation should enter in as little as may be. This criticism applies to all the series recorded, with the exception of the scarlet fever cases. This scarlet fever series we can set aside; the case is not proven, and is at best not really relevant. Nor is much to be made out of the cases of local and postoperative sepsis; serum and surgery are too hopelessly mixed.

The cases of general infection, puerperal fever, and erysipelas are more directly available.

In the series of cases of general sepsis
there are some in which the diagnosis is not quite satisfactory; others, on the other hand, of recovery, which is surprising under the conditions actually shown. Cases recovering after streptococci were found in the blood are surely striking, but it must not be lost sight of that the clinical course of these cases was not unusual, the happy result not always very directly attributable to the serum, and that such recoveries are not entirely unknown where no serum-therapy has been employed.

In the puerperal cases the difficulties are: (1) the cases are mainly isolated observations by different observers; (2) many cases reported are without any bacteriological evidence; (3) the course of puerperal fever is most varied, the prognosis notoriously uncertain; (4) many of the reported cases were efficiently treated surgically as well as by serum.

It is hard to draw just conclusions under these circumstances. The mortality, 32.3 per cent, cannot be called low, even granting that the series includes many desperate cases. It is perhaps not fair to compare this with any ordinary series of cases of puerperal sepsis, but certainly on such figures as a basis there can be no talk of any considerable reduction of mortality.

In individual cases the use of the serum would seem to have helped definitely, but these are more than counterbalanced by cases of streptococcus infection alone where no effect whatever is to be attributed to the serum. The irregularity of course in puerperal fever, the difficulty of distinguishing the results of other treatment from those of the serum, cannot be too clearly borne in mind.

In a proportion of cases, however, there does appear, apparently as a definite result of the use of the serum, a marked improvement in the subjective condition, in the pulse, and often in the temperature. This is by no means constant, and apparently bears little if any relation to the general course of the infection, but it seems definite and must mean something.

In the erysipelas cases, again, the mortality figures are not convincing, for, as Therese points out, the ordinary mortality varies from one to five or six per cent, while Marmorek's figure was nearly four per cent.

Here again there appears the same improvement in subjective condition, pulse, and temperature following injections, but more often in this erysipelas series, and often accompanied by a rapid improvement in the local process. This is noted by Rondot as well as by Marmorek. Unfortunately, even here, Petruschky's experiments with inoculation erysipelas and serum must make us a little conservative in interpreting the clinical notes.

Probably no one will now contend that the antistreptococcic serum is, broadly speaking, effective against streptococcus infections. Beyond a doubt a certain degree of passive protection is possible in the laboratory, and probably something of the sort is possible in man. There seems, in view of recent work, no ground for drawing sharp distinctions between alleged species of streptococci, and though it would be a mistake to assume too close a parallel between the conditions of infection in man and in animals, yet probably a serum really effective in protecting rabbits against streptococci would afford some aid to the human organism in its struggle against a like infection. It is likely enough that this is the explanation of the temporary relief of symptoms so often noted. It does not seem that this represents a strong action against the infection, but it is something, and in many cases a very little may turn the tide.

This seems reason enough to give the serum further trial—as a symptomatic treatment if no more. There seems to be no good reason against its use. Urticaria, erythema, joint pains, etc., are of not uncommon occurrence, but of no great moment. Abscesses at the point of injection, sometimes containing streptococci, are not rare, and would indicate care in using a bacteriologically tested serum. Bué and Thomson have thought the serum a cause of albuminuria, but this must be either unusual or slight, judging by reports.

If the serum is to be used in earnest, it should be used in considerable doses. Probably in many cases the dosage has been too small. To protect a rabbit against a ten times fatal dose required 0.2 centimeters of antistreptococcic serum; this is one seventhousandth the body weight, corresponding to about ten centimeters in man. The potency of different makes of serum varies, and they seem to lose notably by keeping. Hence, while there are no accurate data for dosage in man, yet the problem is not to protect against an infection, but to cope with an infection in full swing, and that with a serum of doubtful efficacy; the needed dose will probably be large, if anything is to be accomplished. The limit of dosage must vary, but the untoward effects above noted are not
frequent, and plenty of cases have borne twenty-five cubic centimeter doses. In one case a total of 1030 cubic centimeters was given, though this was in a case of some duration; there were no ill effects beyond a slight erythema.

There seems, then, some reason for continuing the use of the serum in cases of demonstrated streptococcus infection. Care is needful in selecting the serum to be used; it should be used, if at all, in considerable amount; and above all, until more evidence of its power is forthcoming, it should be used as an adjunct only, and never to supplant or modify other treatment of the case.

WHAT TO DO AND WHAT NOT TO DO IN THE TREATMENT OF CERTAIN OF THE MOST FREQUENT EAR AFFECTIONS.

The Journal of Eye, Ear, and Throat Diseases for January, 1899, contains an article by Haué upon this topic. He thinks that foreign bodies in the ear are of the most frequent occurrence, and that they occur usually in children, but still are found often enough in adults, introduced either from thoughtlessness or to afford relief from earache, and especially toothache. A comprehensive enumeration of the objects that gain entrance into the meatus through accident or intent would be unlimited. They include the most common objects that are accessible, and vary with the country in question (beaps, peas, buttons, beads, paper, in children; rice, pieces of lead-pencil, matches, milk, oil, beer, pieces of cotton, straw, etc., in adults).

How shall the general practitioner conduct himself towards these objects? The patient, usually a child, has first undergone household treatment at the hands of relatives or a teacher, with hairpins, matches, etc., until the body is out of sight in the meatus. The unfortunate child is then taken, not to a specialist, but to the family doctor, who, if inexperienced, thinks it a simple matter to remove the offending object with forceps. The object is grasped, but slips from the instrument. The procedure is repeated more forcibly, with the same result. The child begins to cry, and upon further interference the ear bleeds. The doctor concludes that "the thing is deeper in" than he thought, and that he can do nothing further.

The terrified, loudly crying child is then brought to the ear doctor, resisting with hands and feet every attempt to approach it. We must now "keep cool" and not be betrayed by the excited condition of the child's companions into inconsiderate, hasty action. The child must be held firmly by some one, and especially the head firmly fixed. With very restless, uncontrollable children narcosis must be used.

We must then inform ourselves by means of the speculum and reflector whether the foreign body is really there, and in which ear. Children often in their frightened condition refer you, not to the affected ear, but the opposite one.

Having established the presence of the foreign body with the eye, it becomes necessary to inform ourselves by means of the probe as to the consistency of the same and the depth at which it lies. We then have the right to proceed at once to the removal. How shall this be accomplished? Never with forceps, especially for the commonest objects of hard consistency and smooth surface (stones, beads, buttons, etc.). It must be apparent to every thinking person that a hard or smooth body cannot be held firmly in the branches of the instrument, but, on the contrary, must slip from its arms, even when roughened or dentated, and be thus driven still deeper into the canal.

The sovereign instrument for almost all foreign bodies, especially those that have not been disturbed, is and always will be a common, easily working; not too small syringe (80 to 100 cubic centimeters). With this we will effect a good result in ninety-nine per cent of all the cases that have not been "examined" too much. The ear is retracted forcibly, the nozzle placed against the posterior wall of the meatus, and the liquid forcibly and steadily injected; the *vis a tergo* forces the body out. If the first injection does not succeed, repeat it six to twenty times. If the child is unmanageable, it must be at once anesthetized. Lukewarm boiled water should be used. Antiseptics are unnecessary. Water can be used with all objects that are not hygroscopic. For objects which swell in water we may use alcohol, or equal parts of alcohol with water or glycerin. This method usually succeeds in removing any object.

Having convinced ourselves by many repeated attempts that syringing is really ineffectual, we may then resort to instrumental removal.

Here narcosis is with children unconditionally necessary, and that of the deepest tolerance, otherwise reflex movements will certainly occur. Before resorting to any in-
instrument we should first endeavor to remove the object with the syringe under narcosis, and will frequently succeed. Being convinced that this is really impossible, we introduce a small lever (probe), or better still, a slender spoon, along the part of the foreign body that allows it to pass best behind the object, and by a lever-like motion bring it to daylight.

But how shall we act toward meati which, in consequence of preceding attempts at extraction, display marked swelling and phlegmonous inflammation and discharge? Here especially we must not be led to unseemly haste by the pleadings of the relatives. If there is no fever and no general manifestations, we should rely upon syringing and dressing with antiseptic solutions, either liquor aluminii aceti (diluted from two to three times), or in severe purulent cases strips of gauze soaked in alcohol. Commonly we attain our end in moderate swelling and secretion by simple tamponade with dry gauze. Often enough it happens that the foreign body, loosened by the suppuration, comes out. In any case, decided general manifestations excepted, no kind of instrumental interference should be undertaken, when on account of swelling one can neither feel nor see the foreign body. The denuded bony meatus can be and has been mistaken for a foreign body. One should wait until upon reduction of the swelling a direct view of the object is obtainable.

When the patient already exhibits high fever and evidences of cerebral irritation, operative removal must be at once undergone at skilled hands (loosening the auricle and partial resection of the bony meatus).

We will only add further that living animal parasites can be washed out (flies, bugs) either before or after being killed with alcohol, or chloroform and ether vapor (maggots).

Related to foreign bodies in their removal are the extraordinarily common cerumen plugs. We should never proceed at once to remove such masses with instruments, but they should be softened by the instillation, several times daily for one or two days, of solution of potassa, or sodii bicarbonatas with proportion of 1 to 30. On the third day the mass may be removed without difficulty. We should inform the patient that the deafness and roaring will be temporarily increased by the instillation. That cool or cold water should never be employed for syringing in this or any other ear affection goes without saying.

**MUSCLE ATROPHY AS A CAUSE OF POST-OPERATIVE HERNIA.**

Assmy (Centralblatt für Chirurgie, No. 11, 1899) conducted a series of experiments upon animals with the idea of determining in what wise the danger of hernia after abdominal operations might be obviated. He carried many of his incisions to the right or the left of the median line through the main portion of the rectus muscle, afterwards closing this incision by buried sutures, bringing the various structures which had been divided in close contact with each other. A subsequent examination of these animals showed that there always resulted an atrophy of that portion of the muscle lying between the incision and the mid-line of the body, and that this atrophy corresponded exactly in its features with the wasting observed after division of the nerve supply. As corroborative of these facts the author also observed that after an operation practiced on the human through the rectus muscle, the portion of the muscle lying to the median side of the incision atrophied completely. Upon these facts the conclusion is drawn that the extra-median incision may be followed by hernia not only because the scar tissue virtually stretches, but also because from division of the terminal branches of the intercostal nerves which supply the rectus, this muscle atrophies and hence is unable to withstand the intra-abdominal pressure.

**FORCIBLE REDUCTION OF THE DEFORMITY DUE TO POTT'S DISEASE.**

Ghillini (Revue de Chirurgie, Feb. 10, 1899) has operated on nine cases of Pott's disease and one of rickets for the purpose of correcting by direct force a spinal deformity. In three cases under observation for six months the straight position secured by the application of force has been maintained. In one of these the gibbosity formed an angle of 105°, and involved the bodies of seven vertebrae.

In a child eight years old, one month after correction of the deformity an abscess opened at the point of curvature. The spinous process and the lamina of the second dorsal vertebra were resected. Three months later the child was perfectly well. One case was followed by death, due to disseminated tuberculosis.

The only contraindication to this method recognized by the author is an old and very solid ankylosis.
THE OPERATIVE RELIEF OF BRAIN COMPRESSION FROM INTRACRANIAL HEMORRHAGE.

Warbasse (Brooklyn Medical Journal, January, 1899) concludes an interesting report of two cases by the statement that when a patient has sunk into a state of unconsciousness from compression, a recovery from this state will not occur unless the compression is relieved. While inequality of the pupils is often present, it is not to be relied upon as a diagnostic sign. Sometimes the pupils remain absolutely even.

Wiesman noted that when there was marked dilatation of one pupil it occurred in twenty out of twenty-four cases on the side upon which the extravasation existed. A slight rise in temperature is nearly invariable, and the slowing of the pulse rate is one of the most characteristic symptoms of brain pressure. This is commonly associated with slowing of the respiration; and in the optic nerve are noted signs of venous obstruction.

The first case reported was that of a man fifty-three years old. When first seen he was in a condition of stupor. Neither the signs nor symptoms of fracture of the skull were present. After twenty-four hours, during which the stupid condition persisted, he developed pain in the right side of the head and back of the neck, of which he bitterly complained when aroused. On the third day his pulse-rate had gone down to 38 beats a minute, and there was partial paresis on the left side. The skull was opened in three places by the trephine, and on incising the dura a little bloody serum escaped. This operation was followed by prompt relief of headache, restoration of the pulse-rate to normal, and improvement in the mental condition. The drainage-tube, which had been introduced through the dural opening, was removed on the third day. The patient made an uncomplicated recovery.

The second case had received a blow on the head three days before he was seen. This was immediately followed by coma, persisting for an hour, and afterwards by stupor. The patient could be aroused sufficiently to walk when supported and to answer questions. His pupils were of equal size. Above and behind the left ear over the parieto-occipital region there was a soft hematoma beneath the scalp, but the skull beneath was not depressed. The temperature was normal, pulse 80, respiration 20. An incision into the soft hematoma revealed several lines of fracture about the center of the parietal bone.

On going through the latter an extradural clot was found closely adherent to the dura. At the end of twenty-four hours the patient was restored to a normal mental condition.

THE TREATMENT OF CHRONIC SKIN DISEASES BY ELASTIC COMPRESSION.

Serenin (Centralblatt für Chirurgie, Dec. 31, 1898) reports highly satisfactory results in the treatment of nævi, lupus, and various ulcerating lesions of the skin, by six weeks' treatment with elastic compression. The diseased surface was enclosed in the elastic bandage, which made only very moderate pressure. After from twelve to twenty-four hours the bandage was removed, washed, and after a thorough cleansing of the skin was again applied. Efficacy of the treatment was attributed to the slight pressure, warmth, moisture, rest, and protection afforded by the dressing.

TREATMENT OF FISSURE OF THE NIPPLE BY ORTHOFORM.

Maygrier (Medical Press and Circular, Jan. 25, 1899) having been dissatisfied with the great variety of treatment proposed for fissure of the nipple, and particularly with the failure of all drugs, excepting cocaine, to control the at times very severe pain, employed orthoform in the hope that its distinctly analgesic action might be serviceable. This drug, a crystalline yellowish powder, insipid and inodorous, scarcely soluble in water, extremely so in alcohol and ether, is practically non-toxic. Orthoform was originally introduced as an antiseptic. Subsequent investigations showed that it possessed this power in but a feeble degree.

It is worthy of note that under its contact the deepest burns become almost painless. It has been used with success in tuberculous ulceration of the pharynx, for the relief of the burning pains of open wounds, and for the alleviation of the very intense suffering of herpes zoster. Its action is much more lasting than is that of cocaine, being counted by hours and averaging perhaps half a day. The dermis must, however, be exposed, so that the powder can be brought into direct contact with the nerve terminals. Its essential indication is, therefore, the existence of a raw surface. When this condition is present there is absolute suppression of sensibility.

Maygrier has employed this drug in forty
cases of fissure of the nipples. Without exception the relief was almost instantaneous. He employed it as a direct application to the fissure, the dressing being completed with a compress moistened in a solution of boric acid and covered with a piece of oiled silk; or as a dry application, the gauze being applied over the powder in the dry state; or as a saturated alcoholic solution, drops of the latter being applied on the fissure, after which a dry compress completed the dressing. There was always a slight burning sensation for a few moments, but the operation of nursing was rendered almost painless, especially when the alcoholic dressing was used.

The drug, in addition to its analgesic effect, has a distinctly cicatrizing influence, the fissures healing more rapidly under this than under any other dressing. The average time of cure without stopping nursing was four days.

TREATMENT OF CHANCROID BY RADIANT HEAT.

Kroesing (Centralblatt für Chirurgie, Jan. 7, 1899) hails Audrey's method of treating chancroid as a distinct improvement over both the carbolic acid and iodoform methods, and over that so warmly advocated by Wielander—i.e., the application of heat by means of tubing through which hot water circulates. Audrey's method was practiced by Kroesing, except that in place of the Paquelin he used the galvanocautery. The red-hot point was held, at the most, four millimeters from the ulcer, especial attention being devoted to the borders of the latter. The treatment lasted ten to fifteen seconds, but was not carried to the point of producing blisters. The pain was stated to be bearable. There followed the application a serous infiltration of the ulcer. Edema, which is always moderate, quickly disappeared. Usually but one application was required to make the surface of the ulceration perfectly clean, and where there had been lymphadenitis this disappeared promptly.

POSTOPERATIVE DELIRIUM.

Picqué (abstracted in the Centralblatt für Chirurgie, Jan. 7, 1899) classes under this title all intellectual disturbances following operation; though it must be remembered that many such disturbances are not in the least to be considered as having been caused by operation. Thus certain diseases or conditions from which the patient was before suffering may be responsible; as, for instance, renal insufficiency, or chronic alcoholism. Or delirium may be due to drug intoxication, as is so frequently noticed after the use of iodoform, or it may be due to septic infection. Picqué classes such nerve disturbances as pseudo-deliriums, limiting the term "post-operative psychoses" to those mental disturbances which are apparently dependent upon the operation itself.

These psychoses can be caused by every kind of operation, and are not more frequent after gynecological interference than after other forms of operation. Picqué states that these psychoses are most frequent in children, old men, and hysterical people. There is first a period of excitement commonly observed from the second to the fifth day; rarely does it develop after a week. It usually disappears as quickly as it came. Exceptionally it passes into a chronic condition, and is accompanied by depression and melancholia, particularly after operations which are more or less mutilating. These chronic cases often give a history of heredity.

SERUM-THERAPY IN SYPHILIS.

Neisser (Centralblatt für Chirurgie, Jan. 7, 1898) has contributed to the Archiv für Dermatologie und Syphilis a careful study of the question of the serum treatment of syphilis. The first portion of the paper is devoted to a consideration of immunity upon the common conception of which the whole theory of the serum-therapy is necessarily based.

Although Neisser believes in the immunity which follows the first attack of the disease, he holds that it is not so certain and invariable as to be accepted without further study and corroboration.

The various methods by which experimenters have endeavored to demonstrate the efficacy of an antisyphilitic serum are all discussed and are condemned.

In twenty-eight cases he injected serum, mostly derived from patients in the late period of the disease. These injections were made before the development of general symptoms—often intravenously and often in large quantity. In not one instance was there a positive cure. He also attempted to discover a preventive treatment, hoping that the injection of serum from patients in the early or the late stages of syphilis might protect from the disease the individual to whom these injections were made. In four
such patients syphilis subsequently developed. Neisser ends his article with a strong plea for mercurial treatment.

THE TREATMENT OF PELVIC PERITONITIS.

Stratz (Centralblatt für Gynäkologie, No. 6, 1899) notes that in twenty patients upon whom he performed laparotomy for the cure of inflammation of the adnexa, he lost but one, who before operation had developed a generalized peritonitis; but that only fifty per cent of those who recovered from the surgical operation were made well. The remnant suffered from invalidism for years, in some cases from recurrence. Thus he was led to practice more conservative measures.

In acute cases he applies to the entire abdomen large compresses impregnated with equal parts of ichthiol and lanolin; he also orders rest in bed, baths, and hot vaginal irrigations, at a temperature of from 45° to 50° C. One-half gallon of fluid is used at each irrigation, and the treatment is repeated twice daily. He has devised a speculum which protects the external hypersensitive parts from the hot solution. As a result of these irrigations the temperature usually dropped to normal in from four to eight days, the tenderness disappearing at the same time.

TUBERCULOSIS OF THE MAMMARY GLAND.

Halstead and Le Count (American Journal of Obstetrics and Diseases of Women and Children, February, 1899) state that in the beginning mammary tuberculosis may not present any recognizable symptoms. As the disease progresses the symptoms vary according to the form the tubercular lesion assumes.

In the disseminated nodular or discrete type of the disease the nodules may be either single or multiple. The breast generally preserves its normal size and appearance. In only a few cases is the volume appreciably augmented or its contour changed. The skin covering the gland is normal in appearance, not adherent to the intraglandular mass, and without fistula opening on its surface. On palpation we find one or more nodules, which are movable, hard, and only slightly painful on pressure. Their outline is, as a rule, distinct, though at times they may be ill-defined and apparently merge into the surrounding normal gland tissue. These slowly increase in size, soften, and undergo caseous degeneration or suppuration, and in the end form fistula, from which is discharged tubercular pus. The nodules may, before fistula are established, so enlarge that one or more may coalesce, forming tumors of considerable size, which ultimately terminate by discharging their contents through fistulous openings.

In cases where there are a number of nodules they are usually distributed throughout the gland. When a single nodule is present it is nearly always formed in the upper and outer quadrant of the organ.

The most characteristic features of the disseminated nodular form of this disease are the extreme chronicity of the process and its painless and insidious development. In many cases the nodules remain stationary for years without causing any subjective symptoms that lead the patient to seek medical advice. In the end, however, nearly all become slightly painful, gradually enlarge, and undergo the degenerative changes common to all forms of tubercular disease. When softening has taken place, before the cavities coalesce, fluctuation may be detected. In most cases, however, the cavities are so small that it is impossible to elicit this sign.

The confluent form of the mammary gland tuberculosis is characterized by a more acute onset, greater pain, and rapid enlargement of the breast. On palpation we find a tumor, usually single, varying in size from that of a walnut to an orange, of irregular outline, nodular and fluctuating. The gland is generally uniformly enlarged. The tumor, if single, is usually found in the outer half. This type of the disease is more common than the disseminated nodular form. In many cases fistula form early, and it is in this condition that the surgeon frequently first sees the patient.

In about seventy-five per cent of the cases reported there was a tuberculous adenopathy affecting the axillary glands on the same side as the breast lesion. The disease in the axillary glands, even when secondary, usually advances more rapidly than that in the breast. In some cases the lesion in the axilla is joined with the breast lesion by a band of indurated tissue which can be distinctly palpated. When this is present it is regarded as a characteristic sign of mammary tuberculosis.

As in other forms of tuberculosis, softening and suppuration with the formation of fistula is the natural and frequent termination of all types of mammary tuberculosis. Spontane-
ous healing of tubercular foci in the gland before suppuration takes place seldom, if ever, occurs.

In the first of these, the disseminated tuberculosis of the mammary gland, there is very little or no increase in the size of the organ and the skin is unbroken by fistulae. On section distinct, firm nodules are found, which vary in size from a pin-head to an almond. Their yellowish or wax-colored centers are surrounded by a zone of grayish or bluish-gray slightly translucent tissue, and the separate foci are isolated by healthy gland tissue. The gland tissue immediately adjacent to the alien areas is firmer than normal. Various areas show a diversity in the character of the central portions, some more gray, some more yellowish, and some may be calcified.

In the confluent form the gland is commonly enlarged even to double its usual size, but the enlargement is seldom symmetrical; for example, the external half can be much more increased in size than the remainder of the gland. On section through that part which is judged to be most changed, it is found to be made up of cavities, irregularly spherical and flattened, with multiple diverticula. Some that are apparently separate and independent are found, on closer examination, to be connected by minute sinuses, with neighboring cavities. The walls of these cavities are roughened by small cup-like depressions separated by ridges, giving to the whole an areolar appearance. The lining of these cavities is a soft, grayish membrane, one to two millimeters thick, with here and there yellowish points. Externally it sends fibrous prolongations into the adjacent tissue. The gland tissue surrounding the cavities is of increased firmness for a distance of from two to three centimeters, grayish, pale, and fibrous. In this are small, pinhead-sized, grayish, or finely transparent areas projecting slightly above the cut surface. These minute foci are more numerous in the tissue surrounding than in the wall itself. The larger cavities communicate by fistulae with the exterior, and these channels possess lining membranes similar to those of the cavities. Ordinarily only one breast is affected and the axillary glands are involved.

In the early stages of the discrete or disseminated nodular form of primary mammary tuberculosis, especially in those where no axillary adenopathy is present, a positive diagnosis can never be made without a microscopic examination of the tumor. The conditions most likely to be confounded with tuberculosis of the breast are adenofibroma, sarcoma, simple cysts, carcinoma, and gumma.

In disseminated nodular or confluent tuberculosis of the mammary gland, early removal of the breast and axillary gland on the same side offers the greatest hope for a speedy and permanent cure. Nothing short of this can assure an eradication of the disease. In all cases of primary mammary tuberculosis the prognosis, after such an operation, is excellent. In secondary tuberculosis the prognosis, of course, depends upon the seat and extent of the primary lesion.

In the discrete nodular form, where the disease is limited to one focus of inflammation, the remaining portion of the gland appearing normal, the removal of the nodule together with the gland tissue immediately surrounding it will be sufficient, providing the patient can be kept under observation for some time after the operation. In those rare cases of cold abscess of the breast not associated with tuberculosis of the axillary glands, or in those in which a radical operation is contraindicated, aspiration of the abscess and injection of iodoform emulsion may be employed.

THE TREATMENT OF EPILEPSY, EXOPHTHALMIC GOITRE, AND GLAUCOMA BY RESECTION OF THE CERVICAL SYMPATHETIC.

Jonnesco (Centralblatt für Chirurgie, No. 6, 1899) contributed an article in 1897 upon complete bilateral resection of the cervical sympathetic nerves as a rational treatment for exophthalmic goitre and epilepsy; since which time he has practiced the operation in fifty-four cases. In September of 1897 he limited this resection to the superior cervical sympathetic ganglion in a case of glaucoma, and has repeated this operation seven times. Since August, 1896, he has operated upon forty-three cases of essential epilepsy, one of epilepsy and chorea, one of epilepsy and exophthalmic goitre, eight of exophthalmic goitre, one of goitre and glaucoma, and seven of glaucoma. Of these sixty-one operations, forty-two were complete bilateral resections of the three ganglia and their intermediary connecting nerves. In the remaining operations the procedure was somewhat modified.

As a result of operation on ten cases of exophthalmic goitre, six were cured and four were improved. At least two of these cured cases have been under observation for up-
wards of two years. They were all instances of true primary exophthalmic goitre.

The first result of the operation is the rapid disappearance of the exophthalmus, an improvement in the general condition and of the nervous symptoms. The last thing to disappear is the goitre. This may not lessen in size for months or even a year. Of six acute cases four underwent double resection, the other two resection of the upper two ganglia. Improvement was noted in one case of Basedow's disease, in which a unilateral resection was made. In the three improved cases the disease was secondary.

The author holds that resection of the sympathetic is especially indicated in the primary forms of Basedow's disease, and warns operators against expecting too early a marked result.

Of the forty-five cases of epilepsy operated upon, forty-two were subjected to complete bilateral resection. Six died shortly after operation; but nineteen have been observed for a sufficient length of time to enable just conclusions to be drawn therefrom. Ten are reported as cured, and five of these have been under observation for upwards of two years. Six are improved; two are not improved.

As to the glaucoma cases, the improvement was rapid and surprising.

The evil consequences of this operation are, according to Jonnesco, absolutely lacking.

It is interesting to note in this relation Chipault's communication in the Gazette des Hôpitaux for April, 1898. Of his seventy-one operations, forty-one of which he previously published, with forty collected from general literature, there were no deaths. He noted that to be successful it was absolutely essential that both superior ganglia be removed. The cases in which the cord was resected below the ganglia, or in which the middle ganglia were removed, were unsuccessful. Chipault quotes Jonnesco to the effect that nine out of fifteen cases were cured and four benefited. Chipault's most recent recoveries were first of a child two and a half year's old who had suffered from fits for about twenty-two months (he had them every few minutes), and who had been subjected to futile craniectomy. The right upper cervical ganglia was removed, and in a month the patient was well. The second case was also cured, at least for the one month during which it had been under observation.

THE CURE OF CERVICAL ADENITIS WITHOUT CICATRICES.

Under this title Calot (Revue de Chirurgie, No. 11 Supplement) describes a method which he states will be successful in ninety-nine out of one hundred cases. Adenitis in itself he considers of minor import. The most serious aspect it presents is that connected with the customary scarring incident to operation, which as a rule is practiced on those cases which do not undergo spontaneous resolution. The most unfavorable cases are those which neither become absorbed nor break down and soften.

Resolution is favored by general hygiene and an antiseptic treatment of all the regions drained by the lymphatics running to the infected ganglia; also by sea air. When, after prolonged residence at the seaside, the glands neither soften nor disappear by absorption, Calot injects into them thirty to forty drops of a two-per-cent solution of zinc chloride. This is repeated three or four times every second day, and almost certainly causes softening. When this is accomplished, and at once, when cases present themselves in which the gland is broken down and softened or in which the skin is not yet affected, Calot drives a fine hypodermic needle into the softened material, withdraws a part of it, and injects camphorated naphthol. Thus he always avoids the open operation except in such cases as exhibit an ulcerated, undermined, devitalized skin covering.

THERAPEUTIC INDICATIONS FOR SECTION OF THE CERVICAL SYMPATHEIC NERVE.

Abadie (Revue de Chirurgie, No. 11 Supplement) instances as types of maladies caused by the alterations of nutrition due to permanent excitation of the vasodilator nerves, glaucoma and exophthalmic goitre, both of which, he states, are cured by section of the cervical sympathetic nerve. Other maladies, he considers, could be with advantage subjected to the same treatment, such for instance as the morbid phenomena incident to excitation of the vasodilator of the thoracic abdominal organs. A common characteristic of such maladies is dilatation of the pupil. In this relation, it is interesting to note, Témon reports a bilateral resection of the cervical ganglia for the relief of exophthalmic goitre. The middle and lower ganglia were resected, and for eight days the symptoms were distinctly better, but after
two weeks the condition of the patient was worse than before operation. Two other cases of this nature were treated by partial thyroidectomy. The results in each were entirely satisfactory.

A FATAL CASE OF TETANUS IN THE NEW-BORN TREATED BY SERUM.

MEERKOWSKI (La Presse Médicale, Jan. 14, 1899) reports the case of a child seven days old suddenly taken with rigidity of the jaw, followed by complete opisthotonus and rigidity of the extremities, with paroxysms about every fifteen minutes. The umbilicus was suppurating. Microscopic search and inoculation failed to demonstrate the presence of the tetanus bacillus. Ten centimeters of antitetanic serum, obtained from the Pasteur Institute, was injected twelve hours after the first development of the disease. No amelioration followed the injection, and the child died the following day. The cord lesions were similar to those observed in tetanus.

INTRAMEDIASTINAL ESOPHAGOTOMY PRACTICING THE REMOVAL OF FOREIGN BODIES.

FARGUE (Revue de Thérapeutique Médico-Chirurgical, Nov. 15, 1898) had brought to him a child who three months before had swallowed a sou. The child had wasted much, suffered from pain in the chest, had attacks of suffocating, spasmodic cough, accompanied by expectoration of mucopurulent, blood-stained sputa. Bronchia was especially marked on the left side, and there was vomiting. The symptoms suggested that the sou was fixed and had ulcerated partly through the esophagus. The radiograph showed the coin fixed in the fourth intercostal space to the right of the shadow cast by the vertebral column. It was because of this radiograph that Fargue practiced, contrary to the accepted views of the subject, a right instead of a left posterior thoracotomy. A six-inch vertical incision was made over the angle of the ribs, between the middle line in the general border of the scapula. The sixth, fifth, and fourth ribs were denuded for about two inches of their length and were resected. The third intercostal was clamped. The thorax was opened to an extent sufficient to allow the introduction of the fingers, which were employed to strip the parietal pleura. The edge of the sou was distinctly felt, but it was only by the very tips of the fingers and at a depth of about three inches; moreover, there was sufficient hemorrhage to entirely obscure the operative field. The effort to strip the parietal pleura by following its mediastinal reflection and thus separating it from the right border of the esophagus was unsuccessful. The cellulo-fatty tissue lying directly in front of the vertebral bodies and behind the esophagus was entered, and hence the esophagus was carried forward out of reach. It was impossible to find the interspace between the esophagus and the pleura, and the coin could no longer be felt. The mediastinum was tamponed, the wound was drained, and the upper part was sutured. Twelve days later the coin was extracted by an instrument introduced from the mouth in the ordinary manner.

ANTISEPTIC LIGATURES.

HAEGLER (Centralblatt für Chirurgie, No. 5, 1899) urges the importance of incorporating with ligatures some antiseptic substance which will prevent the development of late abscesses due to infection of the ligatures. He states that he has observed many such abscesses; that some of them did not become manifest for four or five weeks after complete primary healing; that the thin purulent secretion from these abscesses was often sterile both by microscopical examination and by bacteriological test; but that the ligature which should be regarded as their causative agent, if examined would be found to be swarming with microorganisms.

He noted that if a sterile ligature were drawn through the finger of the operating surgeon it would always be found to be, after this process, thoroughly infected with germs. Therefore, as a means of preventing the germs in or upon the surface of the surgeon’s skin from subsequently forming the nidus of a necrotic area, Haegler has his ligatures so prepared that they contain an active antiseptic, strong enough either to destroy the germs or to inhibit their growth. Since the use of this antiseptic ligature, he states that not a single instance of ligature abscess has developed in his clinic.

The antiseptic used is sublimate, the ligature silk. The silk deprived of its fat is impregnated with the mercuric salt, either by boiling for a short time or allowing it to soak for several days in a strong sublimate solution. As a result of this the silk fiber seems to draw to itself the mercury, so that neither washing in water nor in alcohol will remove it.
TREATMENT OF HYPERTROPHY OF THE PROSTATE BY ELECTRO-INCISIONS.

Lewis (Medical Review, No. 6, 1899) reports two cases operated on by the electrocautery as modified from Bottini's instrument by Freudenberg. The first case, seventy-four years old, gave a prostatic history of about ten years' duration. This patient had from four to six ounces of residual urine and was compelled to rise thirteen times in the night. Operation was performed in the office. There was little pain, no hemorrhage, no general reaction. Three weeks after the residual urine was reduced to three ounces. A second operation was performed, but so recently that it is too early to note improvement. In this case the bladder was injected with air instead of water.

The second case, forty-seven years old, gave a prostatic history of about nine years. He was anemic, exhibited a large bubo in the groin, and was almost entirely unable to micturate voluntarily. The prostate was the size of an apple. There was no improvement for seven days after operation—then but a slight and intermittent one. The procedure was repeated about two and a half weeks later. The reporter states that since then the patient has been unable to empty his bladder.

TREATMENT OF BURNS BY POTASSIUM CHLORIDE.

Larger (Revue de Chirurgie, No. 11 Supplement, 1898) employs a saturated solution of potassium chloride as soon as the patient comes under his charge. He states that this lotion is efficacious in all burns, whatever their depth, and that it is especially serviceable in those that are suppurating. The pain, he states, disappears almost immediately. During the whole course of the superficial burn, the dressing consists of compresses wrung out in this solution of potassium chloride, covered in after one or two days with waxed paper. The application is feebly antiseptic, and is not absorbed in sufficient quantity to produce systemic poisoning.

HERNIA OF THE APPENDIX.

Jaja (Revue de Chirurgie, Feb. 10, 1899) has found in 1586 cases of radical operation for hernia practiced by Professor Colzi, twenty-seven cases of hernia of the appendix; twenty-one were uncomplicated, six were strangulated. Usually the appendices showed the evidences of chronic inflammation. The bacteria found were almost without exception colon bacteria of moderate virulence.

Strangulation of the appendix causes the same symptoms as strangulation of a portion of the lumen of the intestines. When the appendix contains solid bodies strangulation is of much more serious import, since it is likely to be accompanied by precocious ulceration or necrosis, with subsequent infection of the general peritoneal cavity. An extremely virulent form of the bacterium coli may be found in the hernial sac. From these facts it follows that an excision of the appendix should be performed whenever it is found in a hernial sac, during the course of a radical cure for hernia.

THE BEARD AS A CARRIER OF INFECTION DURING ASEPTIC OPERATIONS.

Huebener (Centralblatt f. Chirurgie, No. 11, 1899), who has shown by experimental research that a wire muzzle covered with a double layer of gauze will entirely prevent the infection which is otherwise projected into a wound by talking on the part of the operating surgeon or his assistant during operation, is evidently much concerned by Garré's remark that the friction of this muzzle upon the beard of a hirsute surgeon will necessarily release a great number of bacteria and scatter them over the operative field, thus increasing rather than lessening the danger of infection. For the purpose of deciding this important question, he instituted a series of experiments which proved that although the mask did not increase the number of germs which dropped from the beard, this number was in any event sufficient to seriously jeopardize the simple healing of a wound. Although it is true that the bacteria thus disseminated are often non-pathogenic, Huebener found as a result of an examination of twenty-six of his bearded colleagues that eleven were prolific of pyogenic cocci.

To prevent danger from this source Garré has advised that before operation the beard should be bathed in sublimate solution. Bartheney, fearing lest the action of the sublimate should be but temporary, has devised a linen bag into which the beard is thrust. Vulpian, still more radical in his methods, draws over the entire head and neck a gauze bag, the only apertures in which are those for the eyes. A band about the forehead and about the neck keeps this bag in place.
Huebener as a modification of these latter methods has had attached to his muzzle an added sheet of gauze, which by means of tapes attached to its ends can so enclose and tie back the beard that the danger of infection from this source is entirely obliterated.

There are appended to this article two illustrations, showing that this mask is not only scientifically of service, but is also distinctly cosmetic in its effect. Moreover, it is stated that Mikulicz wears it without the least inconvenience, and the bacteriological tests show that it is quite efficient. In the illustrations it is noteworthy that there is no covering for the hair; nor has the danger of infection from this source apparently occurred to the distinguished inventor of the surgeon's mouth, nose, and beard muzzle.

LAPAROTOMY FOR TUBERCULOUS PERITONITIS IN A CHILD OF THREE YEARS.

Sengensse (Annales de la Policlinique de Bordeaux, March, 1899) contributes the history of a case of tuberculous peritonitis which is interesting because of the tender age of the subject, and of the apparently radical cure accomplished in spite of the extremely enfeebled condition and the multiple and serious manifestations of tuberculosis which were developed after operation. Tuberculous peritonitis is rare before the third year. This is true of the asctic form of the affection, which, moreover, is the form most likely to undergo spontaneous resolution.

The child began to lose flesh at the beginning of its third year, and at the same time suffered from diarrhea and distention of the stomach. Upon the surface of the latter were seen large veins. There was evidence of fluid accumulation, and indurated nodules could be felt on palpation. There were scars of former abscesses in the groins and an abscess in the right malar region, which was punctured and injected with iodoform in ether.

The abdomen was first punctured and the fluid was drained off. After this first puncture and evacuation of the fluid, the reaccumulation was rapid; therefore laparotomy was performed, showing tuberculous granulation covering the peritoneal surface. A little powdered iodoform was dusted into the abdominal cavity, which was then closed. There was slight reaccumulation of fluid, followed by absorption and disappearance of the indurated nodules. Later there developed a tuberculous abscess in the leg and one in the arm.

The child three years later is reported as absolutely cured. The abdomen is perfectly soft and shows no trace of either effusion or nodulation.

A TUBERCULOUS LUNG ABSCESS DRAINED.

Salomoni (Revue de Chirurgie, Feb. 10, 1899) holds that intervention in cases of wound of the lung is limited to aspiration of a hemathorax. He operated on two cases of gangrenous abscess, the first of which recovered; the second died from extension of the pathological process to the pleura and then to the other lung. Three cases of tuberculosis were subject to operation. One was completely cured, but died four years later of peritoneal tuberculosis. Another also recovered, but died two years later of generalized tuberculosis. The third case was operated upon in 1896. He was twenty-two years old and fell ill of an acute form of pulmonitis. A suppurating cavity developed which opened by three fistulae. In the discharge were found Koch's bacilli. The general condition of the patient was extremely bad.

A large flap was formed with the base above, and the ribs, from the sixth to the eleventh, were resected. The pleural pouch was opened by the galvanocauteristic knife. This instrument was then carried into two pulmonary cavities, lying above the purulent pleural collection. These cavities were cleansed and packed with iodoform gauze. The upper portion of the cutaneous wound was sutured and the remainder was tamponed.

Nearly two years later the patient suffered from a fistula, and there were symptoms of a tuberculous osteomyelitis of the tibia.

The total number of published pneumotomies for the cure of tuberculosis is thirty-eight; twenty were cured, eight died. From this the author concludes that the operation of pneumotomy is of incontestable utility in the treatment of pulmonary tuberculosis, when this disease occasions unilateral moderately sized cavities.

COMPLETE EXTRIPATION OF THE BLADDER.

Turetta (Revue de Chirurgie, Feb. 10, 1899) states that this operation has been practiced nine times, and of the three men upon whom it was carried out not a single one survived. In his own case the operation
was necessitated by a malignant tumor, which was confined entirely to the vesical walls. The patient was thirty-three years old, and there was no tumefaction of the neighboring lymphatics. There was also excellent physical condition. The temporary resection of the pubic bone was performed, the urethra was cut across, and the bladder was opened from below upward; a small patch of the peritoneum being resected, and the peritoneal cavity then being immediately closed by suture. A uterorectal anastomosis was then performed by means of the ingenious button advised by Boari. On the third day there was an escape of urine through the wound. Sixteen days later the patient died of nephritis.

A SUCCESSFUL TREATMENT OF INTRACAPSULAR FRACTURE OF THE NECK OF THE FEMUR.

Gross (Münchener Medicinische Wochenschrift, March, 1899) had brought to him a patient sixty-four years old, suffering from a left-sided intracapsular fracture of the neck of the femur, which occasioned about an inch and a half shortening. By means of compound pulleys this deformity was entirely overcome, and the entire extremity, together with the pelvis, was enveloped in plaster-of-Paris bandages. As soon as these had become hardened, the patient was allowed to be out of bed. On removal of this dressing the fracture was found to be consolidated and without the slightest shortening.

EMPYEMA OF THE FRONTAL SINUSES AND INTRACRANIAL INFECTION.

Gibson (American Journal of the Medical Sciences, March, 1899) believes that a statement of the features of a case of empyema of the frontal sinuses reported in full by him would be correctly expressed by the following:

First, nasal trouble, starting up a left frontal sinusitis; with persistence of the trouble, beginning caries of the cerebral wall on that side. At a probably much later period infection of the right frontal sinus, either from the left side, but more probably from the nose, or from both. On this side the cerebral wall was the site of a structural defect, so that there was no bony partition between the cavities of the sinus and the skull, and infection of the cerebral covering necessarily resulted.

The autopsy showed that the writer was justified in having relied on a single external opening over one of the sinuses, supplemented by nasal drainage, properly to remove the secretions, as both sinuses were found to be completely free of pus. The failure, however, to make an opening so situated that every part of the sinus could be explored, Gibson now believes to have been a mistake. Certainly, one external opening, unless situated in the median line and of a sufficient extent, fails to give proper facilities for exploration, and this step, in the light of the experience quoted, is absolutely necessary for carrying out an efficient line of treatment.

Tilley recommends a median incision even when only one sinus is affected. He makes an incision from about the root of the nose below, continued upward in the median line for one and a half to two inches; then, having raised the periosteum from the bone over the position of the sinus, the former, with the other soft parts, is drawn to one side, thus fully exposing the bone, which may be removed by gouge and mallet or trephine. The latter is applied to the nasal portion of the frontal bone, between the vertical median line and a line drawn vertically upward from the internal angular process; it will in all cases open the sinus on that side, if one exists. A very manifest advantage of the median vertical incision is that the scar is in the median line, and, being in the direction of natural skin, cleavage is scarcely noticeable a few weeks after operation. By locating the exterior opening as near as possible to the nose, it seems to facilitate access to the infundibulum.

If, on examination, the nose is found to be eroded or perforated, it should be carefully scraped or gnawed away to the extent found necessary. If an extradural abscess is found, it should be explored and any pockets broken up and outlying recesses drained. Whether the dura is to be opened for the purpose of exploration should be judged by the appearance of the process, the intensity and duration of the symptoms. Should the underlying cerebral substance present any apparent changes from its normal consistency, opening of the dura or puncture with the exploring needle, or both, will probably be in order; and if intracerebral suppuration is discovered it must be treated on general principles. The possibility of a complicating cerebral hernia should be forestalled, if possible, by suitable packing.

Irrigation, unless the absence of bony perforation is absolutely demonstrated, should never be employed; by the consideration of the case reported it was apparently the direct
cause of death, setting up an increased tension in the old focus, with rapid spread of the infectious agents. It would seem likewise unwise, if a communication with the interior of the skull has been found, to establish a communication downward into the nose; for a communication between the two cavities should be rigidly avoided. Should the patient eventually recover, and the channel into the skull become firmly obliterated, drainage downward might be instituted at a later period, if the external sinus failed to close. Likewise, after a long continuance of a fistulous tract, its excision and closure by a plastic operation might be possible after establishing nasal drainage.

MOBILE KIDNEY IN CHILDREN.

Comby (American Journal of the Medical Sciences, March, 1899; quoted from Pediatrics) reported to the British Medical Association, at its meeting in July last, that he had encountered eighteen cases of this condition in children in the course of the past several years—so relatively high a number that he is convinced that the condition is high at all ages. Of the eighteen cases, two were aged respectively one month and three months; six were between one and ten years; and ten were above ten years of age. These figures, however, corresponded only to the dates of examination and diagnosis, so that the mobility doubtless dated back further than this. Sixteen of the cases were girls, two were boys—the same proportion of the condition in the female sex observed in adult life. In fourteen of the cases the mobility was associated with dyspepsia and dilatation of the stomach; hereditary syphilis was obvious in two cases; chlorosis in two; enteric diarrhea in one; migraine in one; and psoriasis in one. In nearly every case the affection was latent; in two it had been mistaken for a chronic appendicitis; twice it had been recognized and treated.

As regards the cause, it was impossible to attribute it to pressure of the corset, as the greater number of the patients wore neither corset nor belt. Nearly all were dyspeptic, having gastric trouble or pains in the stomach, suffering perhaps as a result of gastrointestinal distention, to which ill-nourished children are subject. But in the two cases of hereditary syphilis, in whom the floating kidney was discovered post mortem, none of the above causes could have been operative, and the affection must here be considered as congenital. Litten, Gutterbock, Ewald, and Albarran believe all cases to be of congenital origin, with which opinion the author seems inclined to agree, at least to the extent of supposing the kidney to be provided with too long a pedicle, which causes it to float in the abdomen either spontaneously or as the result of pressure or injury. The greater liability of females than males to this displacement must have some connection with the abdominal conformation of the former.

The symptoms are very variable, and do not afford a satisfactory guide to diagnosis; often the affection is absolutely latent. Pain, at times paroxysmal, is sometimes present, and may come on after some unusual fatigue or effort. In these somewhat rare cases the kidney may become twisted and the ureter occluded, causing hydronephrosis, which may be transitory, intermittent, or persistent. Co-prostasis, appendicitis, different cystic or solid tumors of the kidney, perinephritis, and stone are among the conditions to be excluded. Palpation usually reveals the presence of a smooth, rounded, movable mass.

When the affection is latent or well borne, when the pains are moderate or intermittent in character, rest and an abdominal belt may suffice to relieve. Bandaging rarely succeeds. Dyspepsia and constipation, which are so often present, should not be neglected. Should the pains persist or become unbearable, or attacks of peritonitis or hydronephrosis occur, the operation of nephrectomy should at once be made.

A STUDY OF SIXTY-SEVEN CASES OF PRIMARY MALIGNANT TUMORS OF THE SUPRARENAL GLAND.

Ramsay (Bulletin of the Johns Hopkins Hospital, January, February, March, 1899), in summarizing a study of sixty-seven cases of primary malignant tumors of the suprarenal gland, finds the following facts to be true: (1) That while malignant tumors of the suprarenal gland are rare, they should be considered as one of the factors to be eliminated in the presence of an abdominal tumor; (2) that they are somewhat more common in the male sex; (3) that while in a certain proportion the symptoms are fairly well marked, there are many in which no symptom points to the suprarenal origin; (4) that rapid loss of strength, debility, emaciation, digestive disturbances, and abdominal pain are the most prominent symptoms; (5) that skin changes are rather the exception than
the rule; (6) that they run a rapid course, the duration being shorter than usual with a neoplasm in other organs; (7) that the diagnosis is impossible in many, and difficult in all, cases; (8) that a differential diagnosis must be made from other suprarenal diseases, from renal tumors, from hepatic tumors, from diseased retroperitoneal glands, and from cysts and new growths of the pancreas; (9) that the prognosis is always serious, even following a successful operation, from the great frequency with which both glands are found involved, and the tendency to early metastases; (10) that operation gives the only hope of relief, and that it has been successful in two cases; (11) that the principal difficulties in the operation are the friability of the tumor, the great tendency to hemorrhage, and the frequency of adhesions.

THE DISSECTION AND LIBERATION OF THE SPHINCTER ANI MUSCLE, FOLLOWED BY ITS DIRECT SUTURE IN CASES OF COMPLETE TEAR OF THE PERINEUM; WITH A SPLINTING SUTURE PASSING BETWEEN THE OUTER AND INNER MARGIN OF THE MUSCLE.

Kelly (Bulletin of Johns Hopkins Hospital, January, February, March, 1899) states that the prevailing operation in this country is the Emmet, which need not be described in detail, as it is so well known. The operations practiced in Europe for the most part are of a similar nature, or flap-splitting, or Hegar's method. The important principle in the Emmet procedure consists in the application of a series of sutures to an area thoroughly denuded, first closing the bowel, then radiating out from the bowel, over the skin and on to the vaginal surfaces. Emmet further lays great stress upon a tension suture entering and emerging at points outside of and well behind the external sphincter ends and traversing the septum, for the purpose of supporting and keeping all the fibers of the sphincter ends together. Dr. Emmet told the author on one occasion that the devising of this suture cost him more thought than almost anything he had done in gynecology.

Although this operation, as well as the other mentioned, when well carried out, succeeds admirably in many instances, it still leaves much to be desired in that there does remain a residuum of failures, and a considerably larger percentage of cases in which the function is so imperfect at first that we are obliged to wait weeks or months for the patient to gain a satisfactory control; and sometimes in this latter group there are women who will tell you that when their bowels become loose they always find their clothes more or less soiled, while they are also apt to be uncertain about the control of gases.

In order to meet the various objections to the operation as practiced at present, Kelly has devised several procedures. The first important point is the dissection and liberation of both ends of the sphincter muscle, after which they are sutured together with buried catgut sutures, end against end.

The author states that the first point of difference between his own method of treating the sphincter and those of previous operators is a carefully conducted denudation, giving the sphincter a wider berth, so as to separate it from the skin surface, after all the parts have been brought into apposition, by a greater interval. This is done to make the burial of the catgut sutures a safer procedure.

The next important thing is the dissection and liberation of the sphincter ends until one or one and a half centimeters or even more is pulled out free on each side. This has not been proposed before. The ends are then cut off so as to remove the scar tissue, and three interrupted catgut sutures passed through them so as to be ready to bring them snugly together at the proper time.

The rectal wound is then completely closed by a series of interrupted sutures passed close together, so as to make it impossible for any minute particles of fecal matter to press between the stitches and cause an infection. This closure is carried down and over the anus onto the skin area, and then only, after this step is satisfactorily completed, are the sphincter ends brought together and the buried catgut stitches tied. Another important point, which differs from any previous proposition, is the passage of a silk or chromic catgut tension suture directly through the substance of the sphincter muscle half-way between its outer and inner borders. The purpose of this suture is to take the tension off from the buried catgut sutures during the healing process. Kelly prefers this suture to the Emmet tension suture, which is passed well behind the sphincter ends on the skin surface, because his suture acts more directly and does not tend to make the anal orifice so small; it is therefore easier to secure earlier and regular defecation.

The author not only dwells upon the method of securing immediate union of the
external sphincter muscle, but in conclusion insists upon the importance of paying equal attention to securing accurate approximation of the internal sphincter muscle, which must be effected in the following manner: One or two fingers are passed into the torn bowel and the thin septum is brought slightly forward, while with a knife or a pair of scissors the operator splits the septum on its mucous margin and then dissects upwards and inwards, separating the vagina and its columna from the septum in such a way as to isolate the rectum in front and on the sides. By taking a little care and observing the tissues closely, the bowel with the muscle is easily set free, and if the dissection is well done the internal sphincter fibers will be clearly recognized on both sides.

After all the scar tissue is removed the internal sphincter is then united by a series of interrupted fine silk sutures entering and emerging on the mucous surface of the bowel about a millimeter from the edge of the cut. These sutures are passed and tied from above downwards from one and a half to two millimeters apart. It is best to reinforce these rectal sutures by two or three cut gut sutures buried in the septum above them and grasping the muscular coat of the bowel — that is to say, the internal sphincter — and drawing it together over the line of union established by the first set. After doing this the external sphincter is brought together as described above, and the remaining perineal and vaginal portions of the wound united as described in the text-books. The utmost care must be taken throughout not to leave any dead spaces in the septum or about the buried sutures.

After such an operation the bowels should be opened at least every other day by giving a warm oil injection through a soft catheter.

TETANUS SUCCESSFULLY TREATED BY ANTITETANIN.

Galletly (British Medical Journal, Feb. 18, 1899) reports a case of traumatic tetanus successfully treated by serum. The patient suffered from a crush of the finger and exhibited no symptoms of tetanus for nineteen days. Three days after the onset of symptoms twenty cubic centimeters of the antitoxin was injected; a smaller dose was given the next day, and this dosage was continued for four more days, when fifteen cubic centimeters was given twice a day. The next four days ten cubic centimeters was given twice a day, and for the next seven days the same dose once a day. Afterwards recovery was uneventful.

THE PRESENCE OF FOREIGN BODIES IN THE VESICULAR APPENDIX, WITH ESPECIAL REFERENCE TO POINTED BODIES.

Mitchell (Johns Hopkins Hospital Bulletin, January, February, and March, 1899) draws the following conclusions from his investigations:

Foreign bodies, at one time thought essential in appendicitis, are now known to play a much smaller rôle than that formerly accredited to them; and fecal concretions are much more apt to be present as an exciting cause. While many curious and unexpected things are occasionally found, the appendix nevertheless would seem to act especially as a trap for pointed bodies and for small heavy objects like shot or bullets.

Conspicuous among pointed bodies are pins, and their presence is by no means uncommon. Those foreign bodies of light weight, like grape seeds and cherry stones, so popularly assigned as the cause of appendicitis, and against which we are forever being warned, are in reality exceptional, and their frequency is much overestimated on account of the close resemblance of fecal concretions and the lack of careful examination of the bodies described.

TREATMENT OF TUBERCULOUS CYSTITIS IN CHILDREN.

Cumbston (American Journal of the Medical Sciences, March, 1899; quoted from the Boston Medical and Surgical Journal) gives the following outline of treatment for tuberculous cystitis in children:

Cod-liver oil, creosote, and tonics are of value, and iodoform in the form of a pill is highly recommended by Guyon and Reverdin. Locally, an iodoform or guaiacol emulsion is to be injected into the bladder and retained until expelled. The ulcerations may be cauterized and curedt if they be extensive. Being aware of the favorable results obtained from local application of lactic acid in tuberculous laryngitis, the author was led to try this agent in the bladder, and the results obtained in the case reported would appear to indicate that further use of this substance is justifiable.

The indications for suprapubic cystotomy vary according to the end to be obtained.
If it is done to bring about a radical cure, it should be performed only in cases of primary vesical tuberculosis, and then much can be expected from drainage of the bladder. The ulcerations can be directly cauterized with the thermodacry, or even excised through the opening. When this operation is done as a palliative measure—that is, when other foci of the disease are present and the cystitis is secondary—the relief from pain is quite enough to justify its performance.

**TWO CASES OF COXA VARA, SHOWING THE RESULT OF DIVISION OF THE FEMUR BELOW THE TROCHANTERS.**

Watson Cheyne (British Medical Journal, Feb. 18, 1899) exhibited before the clinical meeting of the Medical Society of London two cases showing the results which follow division of the femur below the trochanters and correction of the eversion of the leg incident to coxa vara. His idea in adopting this measure was to bring the foot and leg into the proper position so as to enable the patient to walk, leaving the region of the hip-joint untouched. At the time he performed his first operation he considered the possibility of correcting the deformity by removal of a wedge from the neck of the femur; but the parts were so small, the child being only three years old, that he feared lest he should have trouble in getting a proper correction, while at the same time it seemed almost impossible to hope to maintain the correction in such a young child. The first operation was performed in January, 1893. Apart from the restored usefulness of the limbs, the most remarkable and most unexpected result was that, as a consequence of dividing the femur below the trochanters, the progress of the deformity in the neck of the bone was arrested. This case was exhibited six years after operation.

When first seen the patient exhibited a deformity clearly referable to curvature of the neck of the femur, chiefly characterized by marked eversion of both legs, and greatly diminished inversion—in fact, the feet could hardly be brought around sufficiently to look directly forwards. The trochanters were not above Nélaton's line, the essential deformity being curvature of the neck of the femur backwards. An incision was made into the outer side of the thigh at the upper part of the femur, and the latter bone was divided transversely across by a saw a little below the trochanters. The foot and leg were then forcibly inverted until the normal degree of complete inversion was obtained, and were held in this position while the trochanters were pushed forward. A perforated oblong aluminum plate was placed over the femur opposite the line of division and nailed on to the two fragments by means of tin tacks which had been nicked, thus preventing rotation of the leg outwards during union. The limb was put up in the inverted position, and the wound healed by first intention. Three years after operation an abscess formed over the seat of the former operation, requiring the removal of the plate and tacks.

The second case, operated on two years before exhibition, was three years old. She exhibited marked eversion of both legs, which could not be brought to look quite forwards, diminished abduction, and lordosis. The trochanters were at the level of Nélaton's line. There was anterior curvature of the femora, and flat feet. The child walked with a waddling gait and the knees tended to cross one another.

An operation similar to that just described was performed, the plate still remaining in situ.

The object of the operation has in both cases been completed attained; the legs are in perfect position, inversion and eversion of the feet and legs are normal, and the legs are as useful as if there had never been anything the matter with them.

The left leg, for which nothing has been done, in each case has improved markedly in usefulness, and the eversion has somewhat diminished, though not to any great extent. In both cases, however, the deformity has continued to progress, more especially in the direction of the elevation of the trochanters, which are now about half an inch above Nélaton's line, with the result that the left leg is in each case shorter than the one operated on.

The deformity on the side operated on has come to a standstill in both cases. Why it should have become arrested on the side operated on, while it has progressed on the other, is somewhat difficult of explanation. The trochanters on the limbs operated on still remain at the level of Nélaton's line; while, on the other side, they are at least half an inch higher. Consequently, the legs operated on are longer than the others. Two suggestions appear possible:

The process of repair and consolidation of the bone around the point of fracture may
have extended upwards into the neck of the bone, and led to consolidation and arrest of the softening process, which was leading to the curvature.

The branches of the nutrient artery to the neck of the bone were divided in the operation, and, as a result of diminished vascularity, consolidation of the neck may have been hastened.

**LUNG ABSCESS TREATED BY PNEUMOTOMY.**

Lichtenauer (Deutsche Zeitschrift f. Chirurgie, January, 1899) reports a case of lung abscess treated by pneumotomy and subsequently the closure of the resultant fistula. It is well known that the great cavities, left after the evacuation of an old empyema, are filled rather by lung expansion than by molding of the chest walls to accommodate the lessened thoracic contents. Such molding, however, cannot take place when the parietal and visceral pleura are adherent, and the cavity has been created not by pressure upon the lung but by destruction of its substance.

Lichtenauer’s case (a man fifty-two years old) was injured in the chest by a horse, and some weeks later was troubled by a cough and a period of expectoration. The lower part of the left thorax projected posteriorly and was dull on percussion. The sputum was putrid, containing pneumococci and streptococci. An exploratory puncture, just behind the posterior axillary line in the ninth intercostal space, evacuated thin, offensive pus.

The eighth and ninth ribs were resected, showing that the pleural cavity was empty, that the lung was hepatized, and that there was fibrinous pleuritis. The pleura was sewed and an incision was made into the lung substance in the direction of the exploratory puncture. This evacuated about six ounces of offensive pus, leaving an irregular cavity about the size of a hen’s egg, which opened above into a large bronchus. This cavity was drained and packed. A fistula remained, which shortly closed, opened and again closed, and so remained for some months, when there was reaccumulation of pus and a renewal of the symptoms requiring operation.

The second incision was carried through the old scar and evacuated a large quantity of offensive pus, leaving a cavity the size of a man’s fist. Firm packing was required, because of hemorrhage. The openings of the bronchial tubes into this cavity were occasionally touched with Paquelin’s cautery. Later a further opening was required from the outside because of insufficient drainage, after which elastic compression was applied to the left side of the thorax. This compression was at first disregarded at night, and finally was worn all the time. It was applied for the purpose of accomplishing a gradual mechanical diminution in the left thoracic space, so that the contraction of the scar tissue could diminish or quite obliterate the lung cavity. This end was accomplished in about a month, and six months later the patient reported as perfectly well.

The writer, in commenting upon this case, states that it is one of acute gangrene, later complicated by moderate bronchiectasis. He quotes Quincke’s records, to the effect that of five cases of simple bronchiectasis none were cured, in two the operation failed to reach the dilated bronchus, one was improved, and one suffered from fistula afterward. Of ten cases of putrid bronchiectasis, none were cured, five died, two were operated upon without result, and in three the results of the operation were incomplete. Of these three, two were sent out with fistula and in the third the bronchiectasis cavity was not found. Tuffer out of forty-five cases records seven cures.

Neuber has reported a patient who was living and in good health, though for four and a half years he suffered from a fistula following the opening of a bronchiectasis.

The cauterezation of the dilated bronchus was in the author’s case futile, since obliteration of the cavity by contraction was not possible. The only means by which this cavity could have been closed was by molding the chest wall by elastic compression.

**FORCEPS LEFT IN PERITONEUM.**

Morestin (Vratch, No. 26, 1898; quoted in the British Medical Journal, Feb. 18, 1899) relates a case illustrating the grave results of overlooking instruments when an abdominal incision is closed. In August, 1894, a woman, aged twenty-nine, had both appendages removed for double pyosalpinx. An abscess developed in a suture track and became fistulous. In December, 1894, left parametritis set in, and an incision was made in the iliac fossa. An abscess developed in the cicatrix of the abdominal incision, and on opening a fecal fistula developed. Profuse suppuration ensued, and an incision into the lower part of
the abscess was made through the vagina, followed by drainage. The patient's health improved for awhile, but urine soon began to pass from the vagina, the abscess having communicated with the bladder. The vesico-vaginal fistula seems to have closed spontaneously; but in March, 1897, urine once more dribbled from the vagina, and one month later a parametric phlegmon developed on the right side and was opened. Not long afterwards an end came to the patient's four years' penance. One day she passed at stool a pressure-forceps 4½ inches long. She showed it to her medical attendant, and was at length restored to perfect health.

CANCER OF THE LIP.

Fricke (Deutsche Zeitschrift f. Chirurgie) finds that of 1193 cases of carcinoma of the lip, the upper lip was affected in but sixty-three instances. In other words, this disease is nineteen times as frequent on the lower as upon the upper lip. Moreover, out of 1264 carcinomas of the lower lip, women were affected in but ninety cases. As a further interesting observation, Fricke notes that while in men the upper lip is affected in 4.3 per cent of cases, in women it is affected in 27.4 per cent of cases.

The age of the patient varies from twenty-four to eighty-three years, the average being about sixty years. As to the etiology of the affection, Fricke notes that a very large portion of those affected are workers in the open air, especially farmers. Heredity apparently plays a distinctly minor rôle. Pipe-smoking is a predisposing factor, as are wounds and abrasions. The carcinoma usually begins as an ulcerating single induration.

As to the period at which carcinomatous infiltration of the lymph glands takes place, it is quite certain that simple enlargement or even marked induration does not positively indicate such a change; since glands macroscopically affected on removal have been found to be free of malignant degeneration.

As to the chances for the patient suffering from carcinoma of the lip, Fricke concludes as a result of a limited study that eight per cent will die as the immediate result of operation; thirty-two per cent will suffer from recurrence; and sixty per cent will be permanently cured. The prognosis becomes distinctly bad when the infiltration has reached the jaw or has involved the lymphatic glands or is very extensive. Fricke believes that every ulcerating wart about the lips which resists treatment should be promptly extirpated under local anesthesia by means of a pair of scissors. When the growth has progressed beyond this stage, every anatomically related lymphatic gland which is placed in its typical position must be removed. If the glands are not perceptibly enlarged, they are taken out with the surrounding fat. First the glands, then the tumor, is extirpated. This sequence is important.

An extensive infiltration is dangerous, because it implies almost necessarily lymphatic infection, is likely to involve the jaw, and because it leads the surgeon to perform a more or less incomplete operation from fear of producing irremediable and unbearable deformity. As a rule the incision should be carried two-fifths of an inch wide of all obviously affected tissue. There were only three cases of local recurrence out of 113 operations in which this rule was followed.

Four times erysipelas developed during the course of healing; three of these patients died of recurrence. There was no reason to suppose this affection had the slightest beneficial effect upon the subsequent course of the disease.

A SUCCESSFUL CASE OF STAPHYLORHAPHY.

Although it is comparatively easy to obtain a good mechanical result by the operation of staphylorrhaphy, it is well known that this closure of the palate is in the majority of cases followed by such slight functional improvement that many surgeons have rejected the operation entirely, believing that the interests of the patient are best consulted by filling in the gap in the roof of the mouth by a properly fitted artificial hard and soft palate.

This being the case, the result reported by Lester (Laryngoscope, March, 1899) is particularly gratifying, since his patient was nineteen years of age, and had undergone two unsuccessful operations for the closure of the cleft. Moreover, a skilful dentist absolutely failed to provide a serviceable artificial appliance. His vocalization was difficult, the letters s, z, k, and g being especially trying to him; and during deglutition food always entered the nasal cavity. Expectoration was only accomplished by pinching the nose tightly between the thumb and finger.

The stitches used were of wire; they were left in fourteen days. Conversation was
limited as far as possible, and only liquid food was given for the first ten days following operation. After complete healing of the tissue, the patient was directed to speak in low, deep, guttural tones, using words which contained the letters which had previously been most difficult for him. He completely recovered the power of deglutition, his phonation became almost perfect, and under the various exercises which he was given the resiliency of the soft palate nearly approached the normal.

TREATMENT OF SPERMATORRHEA AND PROSTATIC AFFECTIONS BY PARADIZATION.

Dr. Moritz Popper (Wiener Medizinische Blätter, Jan. 26, 1899) states that the faradic current offers a method of healthful stimulation to the prostate preferable to the mechanical one of massage; that it empties gonorrhreal pus from the gland and ducts; in acute cases lessens hypertrophy; and cures the weakness of the compressor muscles, which is the fundamental cause of sleep pollution, as well as the atony which gives rise to spermatorrhea and prostatarhrea.

UROHEMATONEPHROSIS TREATED BY NEPHRECTOMY.

Loison (Annales des Maladies des Organes Génito-Urinaires, January, 1899) reports the case of a soldier twenty-two years old exhibiting a large tumor in the right flank. He had never suffered from any urinary symptoms, but had received, a month before he came under observation, a blow in the right loin, which though painful had not crippled him. The tumor was the size of a fetal head, bulged out the fellow's ribs, and formed a projection in the flank. It presented the dulness on percussion, the position, the slight mobility, the indolence, and the fluctuation of a fluid tumor of the kidney. The urine was albuminous. Aspiration practiced in the nipple line evacuated only about an ounce of blood-stained fluid, containing phosphates. This intervention was followed by some signs of peritonitis. The next day the patient passed, per urethram, liquid exactly like that evacuated by puncture. A few days later the urine became perfectly clear, and an effort at ureteral catheterization was made by Albarran, but failed. Loison, therefore, practiced a transperitoneal nephrotomy and evacuated six quarts of dark-brown fluid. The cavity was drained and again secreted very abundantly. The secretion continuing for four months, and the remaining kidney having shown itself to be competent to perform the work of the economy, lumbar nephrectomy was practiced. The ureter was found to be tightly strictured at the point where it joined the pelvis. The kidney had been converted into a huge sac, the walls of which contained some remains of kidney structure.

Trouffier, in commenting on this case, states that these bloody collections in the kidney pelvis, when not secondary to traumatism, are due to a preexisting urenephrosis. The two cases which he personally observed were due to a neoplasm partially obliterating the ureter, and thus causing the hydronephrosis, which was later complicated by hemorrhage. In one case there was periodic hematuria, due to the ureter becoming at times flattened; in the other a huge tumor formed in the loin, which was opened by incision, giving vent to a sudden gush of blood which suggested the wounding of a large vessel. A small tumor was found in the hilum. The patient died fourteen months later.

The case reported by Loison was probably one of 'congenital hydronephrosis, bleeding having been due to the contusion of the side, although simple distention without external violence may cause such bleeding.

As to the treatment of these cases, transperitoneal puncture is to be avoided. If the transperitoneal route is taken in evacuating these collections, the peritoneal covering or kidney should be incised and should be sutured to the parietal peritoneum, thus excluding the general peritoneal cavity before opening the collection. By all means the best approach is by the lumbar route.

Bazy reports a case of an enormous distention of the kidney pelvis by bloody urine, cured by transperitoneal evacuation and by pelvic implantation of the ureter, thus forming a direct and sufficient opening between the pelvis and ureter. The hemorrhage in this case was due simply to distention, and was quite analogous to that variety of bladder bleeding which occurs in this viscus when it becomes enormously distended.

Poirier, in the discussion upon this general topic, stated that he recently has removed a kidney affected with chronic nephritis, because of the amount of blood lost through it. The patient, forty-eight years old, had lost rapidly in strength and weight for three
months. The cystoscope showed that the right ureter discharged jets of almost pure blood. This led to the diagnosis of calculous nephritis. An operation, however, failed to show a calculus. The kidney was therefore removed, since it showed signs of marked degeneration.

THE SIGNIFICANCE OF RENAL PERMEEABILITY TO METHYLENE BLUE.

Nesti (Annales des Maladies des Organes Génito-Urinaires, January, 1899), after having reviewed the various works upon this subject, quotes a number of personal observations upon a variety of different affections, such as ulceration of the stomach, chronic interstitial nephritis, parenchymatous nephritis, both active and chronic, pleurisy, etc., and concludes that the method indicates only the permeability of the kidney to methylene blue, and has no other significance whatever. In this relation he notes the fact that people may die of uremia when renal lesion is scarcely appreciable, whilst kidneys almost completely converted to a mass of connected tissue have shown an astonishing degree of secreting power.

GONORRHEAL STRicture OF THE RECTUM.

Berndt (Edinburgh Medical Journal, March, 1899) reports eighteen cases of gonorrhreal stricture of the rectum from Mikulicz’ clinic in Breslau. Four of the patients were of the male sex. The stricture arises independently of ulceration, and is the result of chronic gonorrhea, with inflammatory infiltration of the entire thickness of the wall of the rectum. The condition was preceded by an inflammation of Bartholin’s gland in five cases. There was an additional history of syphilis in six cases. Mikulicz holds, however, that the majority of cicatricial strictures of the rectum are of gonorrhreal origin, whether one succeeds in finding the gonococcus or not. In five patients the infection of the rectum was favored by a very relaxed condition of the sphincter ani.

The stricture is usually found from one to four inches from the anus, but the stenosis may extend as high as the sigmoid flexure. The lumen of the stricture feels tough and scar-like, with a smooth lining; the rectum is often firmly fixed to the surrounding tissue. Hemorrhage is a symptom in nearly seventy-five per cent of the cases, and appears to result from ulceration above the stricture.

The treatment consists in regulating the bowels, in employing antiseptic douches, and in dilating the stricture with bougies, which are to be left in situ as long as possible. The patient may learn to pass the bougies. Division of the stricture by simple posterior incision was performed upon three occasions, but was not successful. A radical operation was preferred in the majority of cases; it consisted in making a preliminary artificial anus, and then excising the rectum. In two patients the artificial anus was omitted, and one of them died of peritonitis. The artificial anus may be closed at a later period, if the new rectum is found to perform its functions satisfactorily.

PERFORATING ULCER OF THE DUODENUM.

The diagnosis and treatment of diffuse septic peritonitis caused by the perforation of a duodenal ulcer is made the subject of a report by Schwartz (Edinburgh Medical Journal, March, 1899). As regards the situation of the ulcer, it is nearly always found in the first part of the duodenum (within two inches of the pylorus in 243 out of 262 cases). In twenty-six cases there was more than one ulcer; in the remainder it was solitary (eighty-five per cent) The anterior wall is its favorite seat. It has a much greater tendency to perforate than the corresponding ulcer of the stomach. Collin estimated that perforation takes place in sixty-nine per cent of the cases, and it usually occurs into the general peritoneal cavity. Preliminary symptoms of disease in the duodenum are exceptional.

The clinical features of perforation are similar to those of perforated gastric ulcer: severe pain in the epigastrum or beneath the right costal margin; rapid development and progress of general illness; the temperature rarely rises above 101°, and may remain subnormal; the pulse is quickened; vomiting is frequently absent, especially in the earlier history of the illness; nothing can be learned by palpation, on account of the early rigidity of the abdominal muscles. The liver dullness is replaced by a tympanitic note. Nothing is passed per rectum.

The condition is very rarely diagnosed with accuracy; it is frequently mistaken for appendicitis or obstruction of the bowels. Operative interference has usually been delayed until it is too late. Out of twenty-five cases, only three recovered from the operation, and of these one died two months later.
of intestinal obstruction caused by adhesions, and another died six months later from the perforation of a second duodenal ulcer. The only hope of success lies in operating at the earliest possible moment. On account of the frequent accumulation of pus in the right iliac fossa and underneath the liver one is apt to be misled, and to regard the lesion as appendiceal in origin.

In view of the very high mortality which attends duodenal perforation, Tuftin recommends that the ulcer should be submitted to surgical treatment before it perforates, and that this treatment had best take the form of a gastroenterostomy.

THE TREATMENT OF INTUSSUSCEPSION.

Murray (Liverpool Medico-Chirurgical Journal, January, 1899) had a careful search made through the records of the Children’s Infirmary at Liverpool, and found that out of 130,000 new patients there were only sixteen cases of intussusception, or roughly one in every 8000. Of these sixteen cases only seven recovered. The age at which intussusception usually occurs is somewhere between the fourth and sixth month of life.

In employing mechanical means of reduction, Murray states that it has been possible to prove that the pressure of the injected fluid should on no account exceed that equal to a column of water three feet high, since otherwise there is a very real danger of rupturing the inflamed gut. He states that chances of effecting reduction by injection are three to one against it. Therefore, Murray advises in all cases primary laparotomy. His personal experience is limited to three cases. In one the intussusception could not be reduced; it was excised and the child died. In the second case the bowel was reduced with great difficulty; the child might have recovered, but unfortunately, being very cold and collapsed at the time of operation, it was placed on a too hot water pillow, and its back and buttocks were so badly scalded that it died.

The third case, an infant six months old, after some hours of fretting and crying, passed blood and mucus per rectum and became collapsed. There was a distinct tumor occupying the position of the transverse colon, but not palpable from the rectum. The intussusception was of the ileocecal variety and was about six inches long; it was brought to the surface through a median incision and was reduced. The infant completely recovered.

In discussing this paper Hawkins-Ambler reported the case of a boy three years old suffering from intussusception for five days. It was impossible to withdraw the incarcerated gut more than half an inch when it began to tear; therefore the ensheathing gut was sewn to the abdominal wound and opened; the gangrenous gut was divided with scissors through this opening, some three inches of it removed, and the obstruction overcome. The child died twelve hours later.

Puzey reported the case of a child aged five years admitted to the hospital in a collapsed condition, with a mass of gut protruding from the rectum. This was made out to include the cæcum and vermiform appendix, the entrance to the latter being demonstrated by probing. The gut appeared healthy but deeply congested and covered with fetid mucus. The child was anesthetized, held up by the feet, and the prolapsed mass was returned within the rectum and pushed up as high as possible; then hydraulic pressure was brought into play by means of funnel and elastic tube, while the intussuscepted lump was manipulated through the abdominal walls. This process was carefully and gradually carried out until the very small lump remaining rested in the right iliac region. At the end of a week no trace of the lump could be felt. The bowels were freely moved after an enema, and a year and a half later the child was fat and well.

INCONTINENCE OF URINE IN SYPHILIS.

Héresco and Druelle (Annales des Maladies des Organes Génito-Urinaires, January, 1899) publish an observation showing the symptoms of tabes and of the cord lesions of syphilis are very much alike, differing only it may be in the fact that the latter yields to treatment. The case that they report exhibited darting pains, complete disappearance of one patellar reflex and diminution of the other, and some of the other well known signs of tabes. There was, moreover, both diurnal and nocturnal incontinence of urine, which lasted four months and had been preceded by retention. This patient was subjected to injections of calomel, the preparation employed being twenty parts of sterilized olive oil to one part of pulverized calomel. The result, as far as the urinary symptoms were concerned, was almost immediate.
Reviews.

As the title of this little volume (which is about five inches long by four wide) indicates, it is designed for self-quizzing and also as an advertisement for many of the textbooks which are issued by this well-known firm of publishers, for the numbers which indicate where the answer will be found, and which are printed after each question, usually refer to a book published by Blakiston, and most commonly to the quiz series. On the other hand, it can be stated that the questions are most of them clear and to the point, and that the little book can be used by students with advantage, and perhaps also with advantage by practitioners who wish to "brush up" their medical knowledge in the various departments of elementary and practical medicine.

This volume of a little over 300 pages is a condensed manual of materia medica and therapeutics, devoting itself chiefly to the materia medica side of the question rather than to the application of the various remedies and the actual treatment of disease, although, on the other hand, in a large number of instances formulae are given to illustrate the method in which the drugs may be ordered. These prescriptions are of course given in the German method and with the metric quantities. We do not believe that the work will have much demand in this country, even if it is translated, because it does not meet the requirements of the average American medical student, but it is one of the best brief books upon this subject which we have seen issued from the German press.

There is less objection to the text in this book than there is to the illustrations, which are crudely executed, although as a rule they are sufficiently clear to carry out the purpose of the author. Little can be said against the volume, but on the other hand it can be said that there are others in the market at the present time which meet the needs of the student microscopist and bacteriologist better than the one before us. The present volume seems to be chiefly a compilation from other books of this character.

The second revised and enlarged edition of this excellent manual covers practically the same ground as that included in the first edition. As is usual in these works, more space is devoted to hemorrhage than the importance, or at least the frequency, of this accident justifies. A considerable part of the book is devoted to bandaging, fixed dressings, and splints and braces. There is a chapter on massage, and an appendix on invalid cookery and on poisons and their antidotes.

The work is likely to prove a useful addition to the somewhat limited literature which is at present adapted to the nurse's use.

The hundreds of medical and dental students who have been taught by Dr. Brubaker in the Jefferson Medical College and Pennsylvania College of Dental Surgery can testify to his ability to render lucid this subject of elementary medical study, which in the hands of a capable teacher is exceedingly interesting, and in the hands of an incapable one equally prosy. The fact that Dr. Brubaker's compend has reached the ninth edition is an evidence that it has met the need of the students for whom he has prepared it, and it is so complete, though concise, that many of the objections to these condensed manuals do not hold concerning it. As a first-rate summary of physiological knowledge it can be cordially commended.

Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFURD, M.A., M.D. OXON., M.R.C.P. LOND.

The London School of Tropical Medicine has weathered the various storms that beset its fetal existence, and in the course of a year or so will have passed into a working activity. The scheme has just come before Parliament, when the money necessary for the buildings was asked for in the civil service supplementary estimates. The scheme approved itself to both sides of the House, as indeed it must do to every thinking man, as the first step towards combating the grievously large mortality in West Africa from diseases of which we know nothing, because
we have had no facilities for studying their etiology. *Vere scire est per causas sciro.* Simultaneously we hear that the afflicted medical staff of the Seamen's Hospital at Greenwich have resigned *en masse.* It is a pity that a technical discourtesy, such as has undoubtedly been offered to the medical staff of the parent institution, should have cast its shadow over the cradle of this very excellent creation of the Colonial Secretary.

The Sixth International Congress of Otology will meet in London under the presidency of Dr. Urban Pritchard from August 8 to 12. The meeting will be held at the examination hall of the Conjoint Board, and the following details have been arranged: On Monday evening, August 7, a preliminary reception will be held by the President. On August 8, 9, 10, and 11, the Congress will be in session, and excursions will be arranged for the following days. The official languages of the Congress are English, French, German, and Italian. The subject chosen for special discussion is "Indications for Opening the Mastoid in Chronic Suppurative Otitis Media," which will be introduced by Professor W. MacEwen of Glasgow, Dr. H. Knapp of New York, Dr. Luc of Paris, and Professor Politzer of Vienna. Intending members of the Congress are requested to send in their names to the Honorary Secretary-General as soon as possible, also the titles of communications with a short abstract. A museum of specimens and of instruments relating to otology will be held during the meeting.

There is a great deal of influenza of a comparatively mild type at present in London, and the mortality returns do not at present show any decline. We are still as powerless as ever to grapple with the disease; each year has its "specific," and now we are being told that cinnamon works wonders. Dr. Grant, of London, as long ago as 1895 recommended its use from his experience of the antiseptic value of the drug in Ceylon, where immunity from severe malaria is enjoyed by those who work in cinnamon gardens. Dr. Carne Ross goes so far as to say that no patient, if promptly and systematically treated, need be on the sick-list, even after a most severe attack, for more than five or six days. He gives the drug either in tablet form or as a strong decoction. He orders half an ounce of decoction of cinnamon, or two tablets, every half-hour for two hours; then the same dose to be continued every hour till the temperature falls to normal. After the temperature has become normal the same dose is to be taken four times a day for four days; the patient is not allowed to leave the house for twenty-four hours after the temperature has become normal. It seems that an essential of success is that the treatment should be commenced within twenty-four hours of the onset of the attack.

At the Clinical Society of London Mr. Arbuthnot Lane read notes of a case of erosion of the ankle-joint, illustrating a new procedure for the complete removal of tuberculous material from the joint. In his previous method of operation he divided transversely all the structures around the joint except the internal lateral ligament, the tibialis posterior, and the flexor tendons of the toes. The divided tendons were carefully sutured, but in spite of this, usually because of infection of the joint previous to operation, they occasionally united imperfectly, and deformity and imperfect control of the foot resulted. In his new procedure, besides the transverse incision through the skin he makes vertical incisions long enough to allow him to expose fully a considerable extent of the several tendons. In the young infant he found he could expose the interior of the joint by dividing only the peroneus tertius and the anterior and posterior ligaments, simply turning the remaining tendons out of their sheaths and hooking them aside. In older children it was necessary to divide the peroneus longus as well high up, cutting through muscular and tendinous fibers, securing larger and more vascular areas in accurate apposition, and keeping the sutured portion at a distance from the joint, and so diminishing the risk of infection. In these children it was better to apply the same treatment to the peroneus tertius as to the peroneus longus.

Mr. Walsham made an interesting communication to the Royal Medical and Chirurgical Society on the treatment of aneurysms by extirpation, with notes of a case in which he had recently performed this operation. In his own case the sac involved the common, internal, and external carotid arteries of the right side of the neck, and a notable feature was the absence of pulsation, so that the nature of the tumor was only discovered after exploration. The absence of pulsation in this case was not due to leaking of the sac, and so presumably was due to blocking of the mouth with clots. The common carotid was ligatured in two places below the sac, and divided between the ligatures; the sac was
dissected up, collateral vessels entering it
were secured as met with, and finally the
internal carotid was ligatured above. The
sac was then removed entire. The patient
made a good recovery. The chief methods
of extirpating aneurisms are: (1) The old
operation of opening the sac, turning out the
clots, and securing the artery above and
below; (2) the old operation, together with
removal of the sac by dissection; (3) the
removal of the sac after the artery has been
tied above and below. Walsham considered
the last of these by far the best, slightly
modified by dividing the proximal artery
between two ligatures, dissecting up the sac,
and finally tying the distal vessels. The con-
ditions most favorable for extirpation ap-
peared to be: (1) Where there is insufficient
room to apply a ligature to the artery on the
proximal side, or where a proximal ligature is
attended with great risk, as ligature of the in-
nominate for subclavian aneurisms; (2) where
a large number of large vessels communicate
with the sac; (3) where other measures have
failed to cure the aneurism; (4) where the
aneurism, as in the popliteal artery, has be-
come diffused, or rupture of the sac or gan-
grenre of the limb is threatened; (5) where
the setting free of emboli, as in carotid
aneurisms, would be attended with risk of
cerebral softening. It was shown from a
tabulated series of thirty-three cases of ex-
tirpation of aneurisms that the procedure had
at any rate this distinct advantage, that after
removal of the whole aneurismal sac the
wound healed much more readily; moreover,
if some of the wall of the aneurism was left,
vessels coming off from it might escape liga-
ture, and so give rise to secondary hemor-
rhage.

We would call attention to a recent com-
munication to the Royal Medical and Chirur-
gical Society by Drs. Williams and Horrocks
on the treatment of pulmonary tuberculosis
by antitubercular serum. The injections were
made with serum from a horse which had
been inoculated with tuberculin, and appar-
ently rendered immune. Twenty-one days
after the last injection a liter of blood had
been drawn from the left jugular vein, the
clot removed, and the serum separated and
mixed with carbolic acid solution. This
serum was supplied for use in sterilized
bottles of ten cubic centimeters each, pro-
tected from the external air with an india-
rubber cap. The bottles were kept in ice,
and, as far as possible, the entire contents of
each bottle used up at the time of injection.
As a rule the syringe, which held ten cubic
centimeters, was filled, and injection made
into successive patients until the syringe was
emptied, care being taken to wipe and ster-
ilize the nozzle after each injection. The
individual dosage varied from one to ten
cubic centimeters at a single injection. At
first the serum was tried on five cases of a
more or less acute character, the object being
to determine what influence a prolonged use
of the serum had on the march of tubercu-
osis, as evidenced by the constitutional symp-
toms, the sputum, and the physical signs.
Passing over the details of the five cases,
the authors, in remarking on the effects of
the treatment, say that the serum produced,
among other things, two most striking effects:
(1) the urticarial rashes which appeared in
four of them, and seemed to be caused by
the carbolic acid contained in the first sam-
ple of serum, as a subsequent series of
injections with serum that contained little
or no carbolic acid gave rise to no rashes;
(2) the swelling of the axillary glands, gener-
ally of both sides, which occurred in all the
patients, and followed all the samples of se-
rum. The effect on the temperature and
pulse was rather irritative than otherwise,
the expectoration increased in quantity, but
there was no diminution in the number of
tubercle bacilli, except in one case, though
in three cases the lung tissue diminished and
in one it increased. Septic organisms were
present originally in four of the five cases;
they disappeared from two and diminished in
number in the other two. The general
condition of the patients deteriorated, though
two of them gained a few pounds, in spite of
pyrexia and severe cough; and at the close
of the treatment the physical signs showed
that the serum treatment had not in any way
checked the ordinary evolution of the dis-
ease, but that tuberculization and excavation
gone on uncontrollably. Experience, how-
ever, taught two lessons—one that the serum
was too strong, that it probably had been
drawn from the horse too soon after inocula-
tion; another that the doses had been in-
creased too rapidly, the greatest average
interval being three days.

Tuberculin seems to have the power of
passing through an immune animal but little
changed, unless it has remained some time in
the animal's system, for certainly the effects
of the serum on some of the patients bore a
close resemblance to those of Koch's first tu-
berculin. The first serum was taken twenty-
one days after inoculation.
In a second series of four cases, patients with phthisis in its early stages were selected, and the serum employed was taken seventy-two days after inoculation, and used in small doses, and persevered with until complete tolerance was established. The results formed a marked contrast to the results in the first series, and there seemed to be no doubt as to its beneficial influence, when administered in a milder form and in less severe cases. The treatment was carried on for longer periods than in the first series, and the patients received from thirty-two to fifty injections, the dose of serum varying from one to five cubic centimeters, but never exceeding the latter amount. The injections were well borne, and in no case was there any local swelling or irritation or rash, either of urticarial or erythematous form, but in all swelling of the axillary glands of one or both sides took place, as in the first set. The temperature was practically unaffected, as were also the pulse and respiration. All four patients gained in weight, and remarkably in general well-being. Cough and expectoration greatly diminished in all, and in one ceased altogether. All showed improved physical signs. In the two cases of consolidation they indicated some limitation of the diseased area; in those of excavation, in one the cavity became quiescent, and in the other it contracted completely. With regard to the sputum contents, lung tissue did not appear at all in the course of the treatment, as it had done in one of the first cases. Tubercle bacilli diminished in the consolidation cases and were absent from some specimens, but they were present in others, and were detected from time to time as long as there was any sputum.

The effect of this second and milder form of antitubercular serum was not tried in cases of advanced or acute tuberculosis.

---

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

The treatment of ulcer of the stomach is at all times difficult, and though most physicians have so far admitted that the best results were furnished by rest and the use of milk, some members of the medical profession have of late taken a new stand. Dr. Gaucher's treatment of the hematemesis due to ulceration of the stomach consists first in complete suppression of all food given by the stomach, and secondly, the use of rectal injections of:

- Bouillon without fat, 25 grammes;
- Wine, 25 grammes;
- Peptone, two large spoonfuls.

Four injections are given daily.

As a means of quenching thirst an enema of a hundred grammes of water can be administered night and morning. By counting in one evacuatory injection, this makes the respectable total of seven enemas a day. Besides this injections of artificial serum are made daily, amounting on an average to about 700 grammes. When there is collapse after a severe attack of hemorrhage an intravenous injection is indicated. In such cases Dr. Gaucher strongly recommends the use of the ice-bag, which must be placed exactly at the pit of the stomach, and which has a most beneficial effect. This treatment should be carried out thirty days on an average; then milk (two cupsfuls) may be tried to begin with, and this dose increased up to a liter, then to two liters, daily. Mashed potatoes and other feculent substances may then be added, and little by little ordinary food administered.

Such is the treatment indicated by Dr. Gaucher, but it has been attacked by Dr. Jorisinne, of Liège, in an article published recently in the Presse Médicale. Dr. Jorisinne starts out by saying that complete rest of the stomach is needed, and this proposition, which has been admitted by all authors, consists, first, in complete rest of the body, and secondly, in complete rest of the organ.

Since Cruevillier's time all authors, such as Strümpel, Vanlair, von Ziemssen, Mathieu, and others, have insisted on the milk diet and on the use of alkales, some, like Debove, going as far as to give very large doses of bicarbonate of sodium. But this is hardly logical, as milk is a very complex food and necessitates the use of the gastric juice. Then there is generally formation of lactic acid. Another point to be considered is that the use of large quantities of milk will be a predisposing cause to dilatation of the stomach, still another factor which will not tend to hasten cicatrization. Another thing is that it has not yet been clearly demonstrated that a slightly acid reaction of the mucous membrane tends to prevent healing of the ulcer. Carbolic, boric, tannic acids in light solutions do not prevent cicatrization. Dr. Jorisinne criticizes also the habit that most physicians have of telling their patients, when they are in better condition, to eat often, but little at a time. Such a rule is
antiphysiological and does not seem to be of any use.

Dr. Jorisinne then describes his treatment, which can be briefly given in the following terms: Complete rest in bed. When there is dilatation of the stomach, an hour or two after meals the patient should be placed on his right side and held in that position by a cushion arranged at his back. Rest for the stomach is obtained by suppressing all food and by using alkalinized water, when the tongue is coated and there is not much acidity. Lime-water is indicated when the tongue is clean, red, and irritated. This should be given at a temperature varying from 30° to 35° C. A fair amount of it should be given, but not much at a time. The contents of the stomach are kept from becoming acid by the use of alkalis; it is quite proper for us to give nutritive enemata. In some cases nitrate of silver may be given—five milligrams in a pill with kaolin; two to three pills are to be given every day. No preparations of iron should be ordered. Ordinary food should be taken up progressively. The author recommended in this article the use of a solution of pep tones as a means of warding off indigestion—two large spoonfuls in a cup of salt tepid water.

The discussion on the treatment of appendicitis has now lasted in Paris about three months, the interventionists and non-interventionists speaking each in turn for or against an immediate operation—Dr. Dieulafay, a physician, professor of clinical medicine at the Hôtel Dieu, being the champion of the cause of immediate intervention; Dr. Tillaux, professor of clinical surgery at the Charité, being on the other side, and holding up as a means of curing an attack of appendicitis the old medical treatment, consisting in the use of ice, laxatives, or opium. However, there have been of late several surgeons who have passed from one camp to the other, and of these the most noticeable is Dr. Gérard-Marchant, surgeon of the Boucicaut Hospital. Dr. Gérard-Marchant some three or four weeks ago had taken a certain stand due to what he had seen in six cases of appendicitis where expectation had proved quite sufficient. However, two or three weeks later he was called to the Boucicaut Hospital by his internes to operate on a young woman showing slight signs of appendicitis, with the exception of the pulse; and on operating upon her he found a perforation. This operation, as he says in his letter, caused him to change his mind as to the advantage of delaying intervention, and he now considers it necessary to always operate on all clearly defined cases of appendicitis.

Dr. Dieulafay has spoken at such length on the treatment of appendicitis that what the medical fraternity call "les gens du monde" have heard or read of his various communications to the Académie de Médecine and believe him to be a surgeon. He undoubtedly sees more cases of appendicitis than any other physician in Paris, and his statistics are therefore more complete in one way than those of other medical men, even though they be surgeons. He cited sixty-six cases where an operation was performed, and gives in alphabetical order the names of the surgeons: Bouilly, Chaput, Casin, Hartmann, Lucas-Championnière, Monod, Gérard-Marchant, Marion, Pozzi, Richelot, Routier, Second—a list which serves by exclusion as a sort of index expurgatorius. Dr. Dieulafay concluded by saying that a patient should never die of appendicitis provided an early enough operation was performed—i.e., twenty-four hours after the first symptoms in acute cases, with considerable reaction; thirty-six when the case was not so rapid.

**THE ABUSE OF QUININE.**

To the Editor of the Therapeutic Gazette.

SIR: In the March number of the Therapeutic Gazette appears a short article on the abuse of quinine, which is good and timely. Probably there is no drug which is so abused by the profession to-day as quinine. Quinine is an antiperiodic and tonic. As an antiperiodic it should only be given in the intermission or remission of fevers, and then in reasonably full doses; as a tonic, in small doses after the fever has entirely subsided. Even as a tonic, if it is to be continued any length of time, it is better to combine it with iron, strychnine, or nux vomica. Then one grain or a grain and a half three times a day will be borne better and do more good than larger doses. A long experience has taught me that this is the proper way to use quinine. In this way we can get the best results from this invaluable drug, and with no injury to the system.

But how do we find it used by a large number of physicians, especially by the younger class? It is given indiscriminately in all fevers, and in all stages of fevers. This I have seen time and again, and know it is not an uncommon practice. This leads me to suspect that there must be a failure on the part of our medical colleges to give proper
instruction on the use of this very important drug. I say very important, but that hardly expresses it; it is invaluable, but it is capable of doing, and does do, an immense amount of harm when abused.

When quinine is given in the fever, as is usually done, in two- or three-grain doses every two or three hours, it increases the fever, raises the temperature, produces nervous disturbance, headache, sleeplessness, and in every way aggravates the suffering of the patient.

The daily use of quinine in large or small doses, for any length of time, to ward off malaria is an abuse of it. It does more harm than good. During the civil war in 1862 my regiment was in northern Mississippi, where there was much malaria. While there I received an order, which originated with the surgeon-general, to deal out to all the men a daily ration of quinine and whiskey. I had previously practiced eleven years in a malarious district and knew the order was wrong, but I obeyed it. And what was the result? Just what I knew it would be. For the first few days the men were jolly; then they began dropping into my hospital. Those who had slight diarrhea had it assume a dysenteric character, with red tongues and feverishness; others came in with a low form of irritative nervous fever. I think in about two weeks I had nearly half the regiment at morning call complaining of one thing or another. I stopped the quinine and whiskey. Such practice is always an abuse of quinine.

Forty years ago somebody in a medical journal advised the giving of large doses of quinine, ten- and fifteen-grain doses, in the early stage of bilious fever, no matter how high the fever was. I tried it. It would break the fever in two or three days, but it did not cure the patients. They were longer getting well than those who received the ordinary treatment. It is an unsafe treatment, clearly an abuse of quinine.

Quinine in doses of ten, fifteen, or twenty grains has been recommended to reduce the temperature, and it will do it; but it is a harsh, unsafe treatment and wholly unnecessary, as we have other remedies which will accomplish the purpose and produce no perturbation or shock to the system.

J. T. Stewart, M.D.

Peoria, Ill.

[While we cannot agree with Dr. Stewart in his views in every respect, we do agree with him in the belief that quinine is abused. —Ed.]

Notes and Queries.

THE PHARMACOPEIAL CONVENTION OF 1900.

To all whom it may concern:

In accordance with instructions given by resolutions passed at the National Convention for Revision of the Pharmacopoeia of the United States of America, held in Washington, A.D. 1890, I herewith give notice that a General Convention for the Revision of the Pharmacopoeia of the United States of America will be held in the City of Washington, D. C., beginning on the first Wednesday in May, 1900. It is requested that the several bodies represented in the Convention of 1880 and 1890, and also such other incorporated State Medical and Pharmaceutical Associations, and incorporated Colleges of Medicine and Pharmacy, as shall have been in continuous operation for at least five years immediately preceding this notice, shall each elect delegates, not exceeding three in number; and that the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Surgeon-General of the Marine Hospital Service shall appoint, each, not exceeding three medical officers to attend the aforesaid Convention.

It is desired that the several medical and pharmaceutical bodies, and the Medical Departments of the Army, Navy, and Marine Hospital Service, shall transmit to me the names and residences of their respective delegates, so soon as said delegates shall have been appointed, so that a list of the delegates to the Convention may be published in accordance with the resolutions passed at the 1890 Convention for the Revision of the Pharmacopoeia, in the newspapers and medical journals in the month of March, 1900.

Finally, it is further requested that the several medical and pharmaceutical bodies concerned, as well as the Medical Departments of the Army, Navy, and Marine Hospital Service, shall submit the present Pharmacopoeia to a careful revision, and that their delegates shall transmit the result of their labors to Dr. Frederick A. Castle, 51 West 58th Street, New York City, Secretary of the Committee of Revision and Publication of the U. S. Pharmacopoeia, at least three months before May 2, 1900, the date fixed for the meeting of the Convention.

H. C. Wood,
President of the National Convention for Revising the U. S. Pharmacopoeia, held in Washington, D. C., A.D. 1890.

Philadelphia, Pa., May 1, 1890.

TREATMENT OF CARDIAC ASTHENIA OF PNEUMONIA.

By Henry L. Elsner, M.D., Syracuse, N. Y., Professor of the Science and Art of Medicine and Clinical Medicine in the College of Medicine, Syracuse University.

The treatment of the so-called cardiac asthenia of pneumonia has been exceedingly discouraging to the profession. The sudden and overwhelming toxemia has often staggered the therapist because of his weakness to cope with it. A persistence in the methods of treatment which have become time-honored and routine has done much to rob the patient of the resistance which is absolutely needed to combat successfully a poison at once malignant and destructive.

To prevent the onset of circulatory embarrassment and to relieve this condition when present in acute pneumonia requires the breaking away from the empirical practices of the past and the acceptance, as indications for treatment, of the conditions which clinical and bacteriological experiences have made positive after faithful observation and experiment.

I fear that we have too long limited ourselves to the consideration of the heart alone when administering to our pneumonic patients, disregarding entirely the condition...
of the peripheral vessels, particularly the arteries.

Riegel* long since demonstrated by sphygmmographic tracings that most infections are associated with reduced arterial tension; Rosenbach‡ emphasizes the importance of the vasomotors in experimentally induced infectious endocarditis; and Buchard‡ at the Tenth International Congress dilated on the baneful influences of bacterial poisoning on the vasodilating centers. It remained, however, for Romberg§ to make a series of experiments and to associate these with clinical data. These have done much to place the treatment of the circulatory failure in pneumonia upon a scientific basis. In the Berliner Klinische Wochenschrift he reports a series of convincing experiments with the bacilli pyocyaneus and the pneumococci of Frankel, made for the purpose of determining the relative importance of the heart and the vasomotor system in the production of the circulatory failure in these infections. He concluded that the circulatory symptoms, which we have considered to be due entirely to heart weakness, are, in truth, intimately associated with demonstrable change in the vasomotors. A literal translation of his concluding sentence would read as follows: "We must consider with the heart weakness the weakness of the vasomotors, and with the cardiac paralysis that of the vasomotors also." Later, in 1896, before the Fourteenth Congress for Internal Medicine, and at the meeting of the German naturalists and physicians in Lubeck, Passler and Romberg¶ reported a series of experiments which serve to prove the relative importance in the production of the so-called heart weakness in pneumonia, of the heart itself, and of the vasomotor system.

Animals were inoculated with the pneumococci and the change in arterial tension carefully measured. To give the many experiments in detail would be tedious; but these were decisive. The experiments made with the pneumococci and the bacillus pyocyaneus, in which rabbits were inoculated, proved conclusively that the vasomotors were weakened and showed evidences of paralysis.

These experiments were carried to a logical conclusion after many days of painstaking work, and as the result we are to day in a position to teach that the toxins exert their baneful influences upon the vasomotor centers in the cord.

These observers, in the report just mentioned, speak of the behavior of the heart as branding the infections experimentally produced. In pneumonia, for a time, the arterial tension is kept up to the necessary height by what they call an excited heart action. Infection with the pyocyanus bacillus proved that the heart action was seriously retarded. Both these observers and all who worked with them, including Bruhns, agree that the circulatory disturbance found in the vasomotor system was due to the effect of the toxins on the vasomotor centers in the cord, and was of far greater import than was the condition of the heart.

In this country Van Santvoord* has done excellent work in this same field. Sphygmmographic tracings were taken in eighteen cases of pneumonia, and these seemed to confirm the conclusions of the German observers. While the experiments to which I have thus fully referred establish the great importance of the vasomotor system, more particularly the vasomotor centers in the cord in pneumonic toxemia, the practical clinician will always, in formulating a rational treatment of the changed circulatory conditions, keep before his mental vision the association of an enfeebled heart with dilated peripheral vessels.

Primarily we are dealing with a toxemia. This leads to the cardiac asthenia, in which we are likely to have not only marked changes in the right half of the heart, but far-reaching degenerative changes in the muscle, heart clots, and vasomotor paralysis. To this must be added the obstruction in the pulmonary circuit. Fortunately the toxemia is short-lived, but its effect on heart and vessels is malignant, and when these suffer the treatment must be radical, prompt, and sustaining.

I must still further preface what I shall have to say on the subject of treatment by remonstrating with all my force against the indiscriminate use of such remedies as lower the vitality of these patients while they reduce temperature. All antipyretics, except

* Riegel: Vollmann's Klinische Vorträge, Nos. 144-145. Über die Bedeutung der Pulsuntersuchung.
† Rosenbach: Arch. für Exp. Path., Bd. ix.

cold, which suddenly depress temperature do so at the expense of vital force, and are apt to rob the patient of needed resistance, or they may cause fatal and sudden collapse. Give nothing which at any time in the course of the disease acts as a cardiac depressant. Let your treatment from the beginning be tonic.

I quite agree with Von Jaksch* when he says “the coal-tar antipyretics from antipyrin to lactophenin have their value, but not as antipyretics in the true sense, but as nervines.” He says “these are indispensable.” This latter statement the experience of the American physician contradicts absolutely. The indiscriminate use of nitroglycerin is a growing evil with the profession of this country. If we have in pneumonia lowered arterial tension from paralysis of the vasomotors, why give a drug which increases that condition? No one denies the paralyzing effect of this drug on the vasomotor system.

It has been demonstrated also that the vagus is paralyzed; thus inhibition is removed from the heart by large doses of the drug, and it is assumed still further by Brunton that the blood loses its power of absorbing and conveying oxygen. These are the conditions which we must seek to prevent.

The writer has frequently seen patients who have been treated with some one of the numerous cardiac tonic tablets which we now find in profusion on the market—all of them containing nitroglycerin with digitalis and a variety of other so-called heart tonics—develop the most alarming symptoms of cardiac and respiratory insufficiency, with rapidly lowering arterial tension, and to whom the firm believers in nitroglycerin have, with renewed energy, given increasing doses of the drug, only to aggravate the symptoms and produce paralysis.

Nitroglycerin may have its uses in overcoming peripheral obstruction where the arteries are tense, sclerotic, or narrowed, against which the heart is laboring. This condition occasionally presents with pneumonia in elderly subjects, and may be associated with interstitial nephritis. My experience with these cases has been very unfortunate. With slight change in arterial pressure reduced by the drug and a slow pulse I have been unable to control the heart; tachycardia finally followed, and the patients died.

But in pneumonia, where we already have paralysis of the vasomotors, it would seem from the experience of the past that nitroglycerin is a dangerous drug, in spite of the fact that one or two authorities of note have recommended it in this condition to relieve the overtaxed and dilated right heart; a condition which it would be far better to relieve by venesection, if all other methods fail, than by the use of a drug which causes still further paralysis.

I have looked into this subject very carefully and fail to find any authority founded upon physiologic experiment which justifies the use of nitroglycerin as it is to day used by many without an appreciation of one or more of the factors which underlie and aggravate the obstructed circulation.

Van Santvoord* in his paper pictures a series of convincing tracings taken from a patient during the acute stage of the disease, “one taken during convalescence, and one a few moments after the latter, when the circulation was under the influence of a very large dose of nitroglycerin.” It is difficult to differentiate the first from the last, so similar are they.

A recent experience with a young physician would have been amusing had it not been pathetic at the same time. He had been taught to bleed his patients “into their own veins” by the use of veratrum viride. The patient was a man whom I had treated for myocardial degeneration, and who fell into the hands of the young practitioner suffering from acute pneumonia. I saw him on the seventh day. The physician expressed himself as anxious to have me see his patient, because he wished to be assured that his treatment was all that could be desired. For seven days this unfortunate victim had received one drop of the strong tincture every hour, and when I saw him in extremis, blue from carbonic acid poisoning, he was still receiving what the young doctor had been taught to consider his concealed lancet.

How many physicians have been misguided and how many lives have been lost from the persistent use of this cardiac depressant it would be difficult to compute. I never saw a case of pneumonia recover which had been rigorously treated with this drug.

The secret of success must be found in the use of such methods as will restore or sustain cardiac strength and arterial tone. There are two drugs which, when properly adminis-

*Van Santvoord: loc. cit, p. 525.
tered, meet the indications presented by the
circulatory changes of pneumonia due to
paralysis of the vasomotor centers and the
dilated condition of the arteries. These are
strychnine and digitalis. This statement is
not new to the profession, and I will occupy
no time in emphasizing it.

I wish, however, to insist upon the ad-
ministration of these drugs hypodermically.
The results are more certain and more
prompt. The strychnine may be adminis-
tered in comparatively large doses while the
patient is being watched by skilled attend-
ants. Digitalin may take the place of digi-
talis. With the large doses of digitalis as
recommended by Petresco* I have had no
experience. How are we to treat the result-
ing cardiac insufficiency? By sustaining the
heart and vessels without causing unneces-
sary wear or tear during these hours of immi-
nent danger. To bring to your notice my
method of accomplishing this end is the ob-
ject of this paper.

The profession has long since learned the
value of the diffusible stimulants. Unfortu-
nately their effect is evanescent; hence my
plan of treatment includes the administration
of these at very short intervals during the
continuance of cardiac asthenia. The stimu-
lating effect must be continuous during the
critical period. The remedy must be re-
newed before the preceding dose has lost its
effect. In no other way can we accom-
plish the desired result.

During the past I have treated this condi-
tion by administering, every fifteen minutes,
fifteen drops each of the compound spirits of
ether, aromatic spirits of ammonia, the com-
 pound spirits of lavender, and the tincture of
valerian. This is kept up day and night until
the pulse shows improved tone and the heart
action is decidedly better. The valerian is
added because of its quieting effect when
administered in these small doses with the
diffusible stimulants. Occasionally we meet
patients who have been unable to retain the
mixture when it contained valerian, hence we
have been forced to omit it and to substitute
either pure whiskey or brandy in correspond-
ing doses. If the Hoffman's anodyne is dis-
tasteful, it has been omitted and the dose of
the ammonia and lavender has been doubled.
The frequent administration of the compound
has not seemed to annoy the patients, for, as
a rule, they are not awake longer than is

1891.
A REPORT OF TWO CASES OF LAPAROTOMY FOR PERFORATION IN TYPHOID FEVER.*

BY WILLIAM J. TAYLOR, M.D., PHILADELPHIA,
Attending Surgeon to St. Agnes' Hospital and to the Orthopedic Hospital and Infirmary for Nervous Diseases.

The subject of operative interference in cases of perforation of the bowel in typhoid fever is of such importance that I make no apology in bringing before you this evening the report of two laparotomies performed for this condition during the past few weeks, at St. Agnes' Hospital. Unfortunately, death occurred in both instances, but in view of the very fatal results in these cases if left to themselves, I feel that the attempt to benefit them was not only perfectly justifiable but imperatively demanded.

Laparotomies for intestinal perforation in typhoid fever have, of late, been very thoroughly discussed in Dr. Keen's work on "The Surgical Complications and Sequels of Typhoid Fever," by Finney in the Annals of Surgery, 1897, vol. xxv, p. 233, and by Cushing in the Johns Hopkins Hospital Bulletin, No. 92, for November, 1898; and I will, therefore, attempt little more than to give the histories of these two additional cases and a few conclusions that seem to me worth emphasizing. In all instances where perforation has occurred, the patients were already seriously ill from the disease, and we could, therefore, hardly expect a low mortality, especially where the additional element of an infective peritonitis is considered. Cushing states that in thirty autopsies held in fatal cases of typhoid fever at the Military Hospital at Fort McPherson, perforation was found to have caused death in six instances, one of these being of the appendix. This would attribute to perforation twenty per cent of all deaths, and as according to the latest German statistics (Gesselewitsch and Wanach, quoted by Cushing) ten per cent of the entire number of fatalities in typhoid fever are due to perforative peritonitis, its consequences need not be emphasized.

Cushing states that there were probably 2000 deaths from typhoid fever in the field hospitals and elsewhere during the late Spanish-American war, and if we accept these latest statistics as correct ten per cent, or about 200 of these deaths, were from perforation of the bowel and the resulting septic peritonitis. He stated he did not know of a single instance where operation for relief of the perforation was resorted to, but Dr. De Forest Willard at the December meeting of the Philadelphia Academy of Surgery reported a case of a soldier at the Presbyterian Hospital, upon whom he operated in October last. Dr. Nicholas Senn (Cushing) stated that although he saw hundreds of cases of typhoid fever during his military service, he was only called upon once to operate for perforation, and as the patient was moribund at the time, he refused to do so. 'Certainly very many of these cases should have been subjected to operation and an attempt made to save their lives. With Finney's statistics before us of fifty-two cases of perforation of the bowel in which operation was done with seventeen recoveries, or 32.68 per cent, and which on revision by eliminating all possible sources of error in diagnosis makes a total of forty-seven cases and thirteen recoveries, or 27.68 per cent, and Dr. Keen's table of eighty-three cases and sixteen recoveries, or 19.36 per cent, we should urge the necessity for operation, especially when the known mortality without operation is about ninety-five per cent. Many of the reported cases of perforation of the intestine in this disease which have recovered without operation are probably due to the occurrence of a perforative appendicitis in the course of the fever, for if there be a perforation of the appendix the ulcerative process may be slow, thus giving sufficient time for the walling off by adhesive lymph from the general peritoneal cavity and the formation of a circumscribed abscess, as we sometimes see in ordinary appendicitis.

In two instances which have come under my own observation, postcæcal abscesses formed and worked their way into the right flank, where they were opened and drained, the patients making ultimately good recoveries. In one of these cases the diagnosis of typhoid fever was unmistakable; the patient was under the care of Dr. H. A. Hare, and I had the good fortune to assist Dr. Keen in the operation. In the other case, a young girl at St. Agnes' Hospital, the diagnosis was probable but not positive.

General septic peritonitis has necessarily a high mortality, and it is only by a very early recognition of the occurrence of perforation and immediate operation that we have any chance of success. Cushing lays down the rule, which is certainly well worthy of consideration, that "any abdominal symptoms

* Read at a meeting of the College of Physicians, April 3, 1899.
occurring in the course of the fever are as urgent an indication for surgical consultation as is the appearance of pain and tenderness in the right iliac fossa under all occasions, and that only when this is fully realized will the mortality of these cases approach the low percentage reached in operations for acute perforative appendicitis or perforating gunshot wounds of the abdomen."

I believe, to be successful, the abdomen should be opened at the earliest possible moment after the diagnosis is made, and that no delay whatever should be permitted for reaction or, indeed, for any purpose whatever. In these cases which I report to-night the abdomen was opened within four hours in the first instance, and within two hours in the second, and in both instances a general septic peritonitis was present. The most important point in my estimation is that of diagnosis, and I hope very much to hear from the physicians present concerning it.

Can a diagnosis be made sufficiently early to warrant operation before a general septic peritonitis has developed—that is, in the preperforative stage?

Do recoveries ever take place after perforation of the bowel has occurred, without operation? Fitz remarks: "Since perforation of the intestine in typhoid fever may take place without any suggestive symptoms, and since suggestive, even so called characteristic, symptoms may occur without any perforation having taken place, it must be admitted that recovery from such symptoms is no satisfactory evidence of recovery from perforation."

The symptoms usually given as denoting perforation are sudden and severe abdominal pain, persisting with increasing intensity (in one of my own cases there was severe pain for a week, and in the other for several days, before the perforation occurred), with nausea and vomiting, and a sudden fall in temperature; but in one of Cushing's cases the temperature was 105° F. at the time of operation, and the pulse was 170. This patient complained of severe abdominal pain and general tenderness, somewhat more marked on the right side, was restless, with pinched expression, while his color was cyanotic, the lips blue, and his extremities blue and cold.

The absence of liver dulness is not a physical sign of special value. In my first case the liver dulness was absent, as there was great tympanites, but in my second case this dulness was present. Finney mentions this absence of dulness as being noted in only five out of thirty-five cases.

Marked rigidity of the abdominal wall, a board-like condition as it is frequently described, is certainly characteristic of serious intra-abdominal inflammation, and I consider it of great importance in aiding us to decide upon operative interference.

All of these symptoms are those of beginning septic peritonitis, and show a very alarming physical condition, with the depression consequent upon a violent bacterial poisoning. The possibility of a condition of preperforative stage of ulceration undoubtedly exists, with a localized area of inflammation of the serosa, either with or without the passage through the intestinal wall of microorganisms. This is exactly similar to the preperforative stage of appendicitis and is indeed more serious, as the ileum is freely movable and less likely to form adhesions to other tissues and the formation of a circumscribed abscess. In my second case there was a mass of lymph almost surrounding the perforation in the ileum and firmly attached to the serous coat of the bowel, evidently an attempt, but without success, to wall off the perforation. In one of Cushing's cases this preperforative stage was recognized and the operation done, with the satisfactory result of saving life. It may be that adhesions take place between the omentum and the bowel, as has at times been reported, but this is so theoretical that it cannot be considered as a practical possibility; although, as is shown in the specimen which Dr. Miller has brought here to-night, a perforation may occur and be closed by an omental adhesion. Fatal septic peritonitis may be present without perforation, as had been demonstrated in numerous cases, but we all know a septic peritonitis without operation and drainage is terribly fatal, and this possibility should urge us more strongly to operate in all cases where it is suspected.

Case I.—A man, aged thirty-four years, was admitted to St. Agnes' Hospital, March 3, 1899, suffering with typhoid fever. He had been sick for some time, and it was difficult to fix the exact date of the disease, but presumably it began about the 22d of February. He had been under the care of Dr. Stevens, and his condition had grown steadily worse, having had a hemorrhage of the bowel the day before; the pulse was poor and tympany increased. March 8, about the eighteenth day of the disease, between eleven and twelve, he had all the symptoms of perforation of the bowel, with vomiting, and a drop in temperature from 102½° F. to normal.
Dr. Stevens saw him shortly after twelve o'clock and advised that he be turned over to me for operation. I did not see him until three o'clock, and found him with a greatly distended belly, short respirations, pulse almost imperceptible, and finger-nails and lips rather blue. He had horrible pain, which was especially severe over the right side of the abdomen; his whole condition was one of profound poisoning. The only possible chance of saving his life being an abdominal section, I laid the matter before his mother and sisters, telling them I considered his chances for life without operation absolutely nil, while with operation there was a chance, but a very slim one, that he would recover, and that I considered it my duty to give him that one chance. They accepted the proposition and told me to use my own judgment. All preparations were made for a rapid laparotomy. Ether was then administered, and in the course of a few minutes, after some struggling, his respirations became easier and his pulse fuller in volume, so that it could readily be counted. As soon as he was narcotized I rapidly opened the abdomen, and typhoid feces spurted out at least twelve inches. I quickly enlarged the incisions, pulled out the small intestine, rapidly passing down to within about ten inches of the ileo-caecal valve, when I found a perforation of the gut through an ulcer which would admit the end of an ordinary lead-pencil. All round this ulcer the tissues were thickened and congested, and his condition by this time was so threatening that the ulcer was simply invaginated and the peritoneal coating closed over it, with two layers of sutures of fine silk. The abdomen was then washed out with sterile salt solution, and some stitches of silkworm-gut introduced into the belly wall. Before, however, all these latter were in place, death occurred.

From the size of the opening in the gut and the mass of fecal matter in the belly, it does not seem possible that an earlier operation would have had any effect, unless it had been possible to have recognized the preperforative stage, and by operation have anticipated the violent septic peritonitis. The whole time occupied in the operation from the beginning of etherization until the completion of the operation was just twenty minutes, and it must have taken at least eight minutes, if not ten, in the etherization before the abdomen was opened.

Case II.—A man, aged forty-seven years, was admitted to St. Agnes' Hospital March 16, 1899, having been ill with typhoid fever ten days, and for several days he had had severe abdominal pain, but no hemorrhage. On March 28, the twenty-fourth day of the disease, at 11:45 at night, the nurse discovered that his temperature had suddenly fallen from considerably over 103° to below normal; he complained of an intense pain in his abdomen, had vomited, and his condition was poor, but there was little evidence of shock. The resident physician saw him within fifteen minutes and diagnosed a perforation of the bowel. I saw him about twenty minutes past one, an hour and a half having therefore elapsed since the time of perforation. His temperature was then normal, his respirations rapid, pulse very rapid but of fair volume. He had been delirious for days and his abdomen was tympanitic, but not very much distended; there was great pain on pressure, and even a slight touch would rouse him from his stupor and cause him to complain. Liver dulness was present. The abdominal muscles were absolutely board-like. From the sudden and rapid fall of temperature, the vomiting, the great pain, and the board-like condition of the abdominal wall, I felt sure that there was an intestinal perforation. He was therefore given ether, the abdomen was rapidly opened, and as soon as the incision was made into the peritoneum gas escaped, but no fecal matter, only a thin serous fluid. The intestines were very much distended and popped out of the wound; they were caught, drawn outside, and a rapid search of the small intestine made down in the direction of the caecum, where a small perforation was plainly seen in the ileum, about eight inches from the caecum. This opening was not larger than the head of a small pin, and gas escaped, but apparently no fecal matter. There was a marked general peritonitis and about the perforation there was evidence of the deposit of lymph. The whole peritoneal cavity was filled with colorless fluid, evidently the result of intense congestion. The small intestine was in very good condition. There was no pus, marked ulceration, or thickening, except about the point of perforation. The ulcer was invaginated, two rows of silk sutures rapidly placed in position, and the abdomen washed out with normal salt solution; drainage was introduced and the wound closed by through-and-through silkworm sutures. His condition throughout the operation was without change, his pulse remaining good and his respirations somewhat easier after the belly was opened. He passed a
very fair night, his temperature in the morning being 102°, the pulse fair, and on the whole his condition was not materially changed by the operation. Death occurred in twenty-one hours from septic peritonitis.

I believe that cases of typhoid with pronounced abdominal symptoms should be looked upon as nearing the preoperative stage, and more especially all cases in which hemorrhage of the bowel has been noted, for without ulceration the possibility of severe hemorrhage is difficult to understand. Osler states that death occurs in from thirty to fifty per cent of all cases of hemorrhage of the bowel. I should much prefer to open a few abdomens without finding true perforation of the bowel, if I could discover evidence of deep ulceration of the intestinal wall, as it would give an opportunity for reenforcing the weakened wall of the gut by proper suturing, and providing free drainage for commencing general peritonitis.

The danger from operation in these cases is undoubtedly great, and when the shock is very profound may sometimes hasten by a few hours the fatal issue; but I do not believe it wise to wait for reaction, as Dr. Keen suggests, for the shock and lowered temperature is due to the large amount of septic material in the abdominal cavity and to the resultant purulent peritonitis, and not to the shock of the perforation of the bowel. The fact that the greatest number of recoveries occurred (see Dr. Keen's tables) when the operations have been performed within the second twelve hours only carries out this contention; they are, as a rule, the cases where the perforation is small and the onset of the peritonitis slow. Our chances of success are in inverse ratio to the size of the opening in the gut, for the smaller the perforation the slower the extravasation of the contents of the bowel, and, necessarily, the milder the type of infection and degree of shock; while on the other hand, the greater the fall of temperature, the greater the degree of shock and general constitutional depression, the larger the opening, and the more overwhelming the septic infection. In these latter cases I fear our results will always be most disappointing, and it is only by an endeavor to anticipate, to form our diagnosis in the preoperative stage, and to operate early, that we can hope for success.

There are very few of us who would wait for reaction before operating upon a case of acute perforative appendicitis with general septic peritonitis, for if we wait for reaction our patients will have passed beyond the point when they can be benefited; and, indeed, many surgeons now decline to operate at all in these cases. I admit the prognosis in all cases of septic peritonitis is very bad, but I have seen some few patients absolutely snatched from the grave by freely opening the abdomen and draining its septic contents.

Typhoid patients have a wonderful amount of vitality and stand operative interference and many surgical complications remarkably well, providing you can eliminate the overwhelming depression of a septic peritonitis.

I believe that in careful and repeated examinations of the blood in all cases of typhoid fever with severe abdominal symptoms, and indeed, if it be possible, in all cases of the disease, we will find a very valuable aid in arriving at a correct diagnosis, and it will enable us frequently to operate much earlier than we otherwise would possibly feel justified in doing. Cabot (Clinical Examination of the Blood) and Thayer (Johns Hopkins Hospital Reports, vol. iv, No. 1, p. 83) have demonstrated that during the fever there is a tendency for the number of white corpuscles to diminish, and with the onset of any acute inflammatory process the number of white corpuscles is largely and suddenly increased. Cushing has shown in two of his cases that there may even be a diminution in the number of leucocytes in the blood after the onset of peritonitis, when there is a large outpouring of leucocytes into the abdominal cavity; and, at first, this might seem to destroy this means as an aid to diagnosis. If, however, the blood be carefully examined and a marked and sudden leukocytosis demonstrated, corresponding to the increase in abdominal pain, and which again abruptly diminishes, we should at least suspect perforative and septic peritonitis.

I would here quote Finney's conclusions as thoroughly expressing my own belief: First, of all the so-called diagnostic signs of perforating typhoid ulcer, most reliance is to be placed upon the development of an attack of severe, continued abdominal pain, coupled with nausea and vomiting, and at the same time a marked increase in the number of white blood corpuscles; secondly, the surgical is the only rational treatment of perforating typhoid ulcer; thirdly, there is no contraindication to the operation, surgically speaking, save a moribund condition of the patient.

I would therefore urge most strongly that all cases of even suspected perforation with great abdominal pain, if accompanied by a
marked increase in the number of white blood-corpuscles, be subjected to an abdominal section, that a rapid search be made for a perforation in the last two feet of the ileum, the appendix inspected, as well as the cecum, and if no opening is discovered, an examination made of the sigmoid flexure of the colon. Any especially inflamed spots should be covered in by stitching the sound serous coating over them.

Cushing has shown how necessary this is in the report of his case, where the abdomen was opened three times, first for perforation, secondly for strangulation by a band of adhesions, and thirdly for a second perforation of the bowel and fecal extravasation.

Unquestionably a number of cases will be operated upon, if this plan is pursued, without any perforation being discovered, but if drainage be practiced we will of necessity save many lives which would otherwise be sacrificed.

The vast majority of cases of suspected perforation submitted to operation where no opening in the gut has been found have recovered promptly from the surgical interference, and in some instances at least with apparent beneficial effect upon the course of the disease.

Welch, of Johns Hopkins, has shown that it is quite possible for microorganisms to pass under certain conditions through the inflamed wall of the gut without there being any true perforation, and bearing this in mind, we should always drain the abdomen.

I shall not go into the question of the technique of the operation, for with this we are all familiar in our work on the appendix, but to insist upon the necessity for the utmost speed consistent with thorough work. The incision should be made to the right of the median line, as by far the greatest number of perforations are found in the lower end of the ileum, and, if there be need, a second opening made on the other side of the abdomen, if free drainage cannot otherwise be secured.

**THE EVOLUTION OF MODERN THERAPY.**

*By Simon Baruch, M.D., New York, Physician to Hood Wright Memorial (formerly Manhattan General) Hospital, and Consulting Physician to the Montefiore Home for Chronic Invalids.*

What is the status of therapeutics to-day? How does it compare with that of the past?

*Address before the Society of the Alumni of the Medical College of Virginia.
sons, children, old people, and pregnant women. With therapeutic intuition he regarded inflammation and fever as manifestations of the conservative tendencies of the organism against which so heroic a measure was likely to react unfavorably. Although he bled freely in inflammatory conditions, he constantly cautioned the wisest care and attention to the condition of the patient's strength and vitality, his aim being "to relieve pain, moderate perturbed febrile movement, and promote crisis." For this reason he preferred local bloodletting. His plan of treating disease was cautiously watchful of the indications of nature (quos vis), by which he meant the organism. In his work on epidemics he writes: "We must do nothing foolishly bold, but be quiet and wait; if one does not help the sick, one at least does them no harm." In fevers he advised an abstemious diet, barley water, as a drink water and honey. Of medicines he used emetics, laxatives, and revulsives; radix heliebori, asses' milk, and juice of euphorbium. All his writings display an acuteness of perception which makes his observations valuable. The noble spirit which he sought to inculcate is evidenced by the Hippocratic oath, which commands the physician to live virtuously and piously and to preserve his art.

The enormous proportions which bloodletting assumed among many succeeding generations of physicians testify not only to the dominance of this remedial agent, but its rise and fall illustrate the varying conceptions of the aim of therapeutics which held sway at various times. I can therefore offer you no more striking illustration of these therapeutic conceptions than by briefly tracing the fate of this chiefest of so-called curative agents throughout medical history. The death of Hippocrates (366 years B.C.) resulted in more or less desuetude of his philosophical and rational teachings. Professing adherence to and extolling the latter, his scholars and their followers gradually swerved from the lines of strict bedside observation and deduction, which he had inculcated as the first duty of the physician. They attempted to construct systems of medicine by substituting their own speculations for the more simple methods of the Nestor, and thus they fell into false practices. There were a few exceptions among these impracticable men, who urged bloodletting and purgation in all diseases. Chrisippus and his pupil Erisistratus held boldly to the master's teachings and insisted that spoliative methods were contrary to nature. Indeed, few physicians at the present day excel Erisistratus in the wise ordering of abstention, baths, enemata, and other harmless therapeutic measures. Phillipus of Cos and Serapion (260 B.C.) formed the empirical school, based upon the pure Hippocratic doctrines. They cast aside all dogma and hypothesis, and depended solely upon bedside observation. They were extremely cautious with venesection, and regarded plethora and retained excretions as the principal etiological factors. They depended chiefly upon enemata and laxatives, and resorted to bleeding only when these failed, avoiding it always in chronic cases.

When the exponents of this sensible practice passed away, their pretended followers deviated from their teachings and lapsed into the most crude empiricism. Medicine was rescued from the latter by Asclepiades, who adopted as a motto of treatment tuto cito et iucunde, depending chiefly on diet, rubbing, exercise, rest, and bathing. By reason of his great popularity in Rome his propaganda for bathing in health and disease obtained enormous success.

Galen is a familiar name. Being a man of culture and possessing great oratorial powers, he so skilfully constructed a system of medicine by a conglomeration of all former doctrines and practices that it endured for thirteen centuries. His fantastic ideas of the residence of the cardinal powers of life in the heart, the brain, and liver, and his doctrine of the four temperaments based upon the predominance of mucus, blood, yellow and black bile, stamp him as an idealist. Still he insisted upon the Hippocratic doctrines, and by his remarkable cures he acquired enormous repute, which is evidenced by his becoming physician to the Emperor Marcus Aurelius. He advised bloodletting as the surest remedy in plethora, in chronic ailments due to suppressed hemorrhages, and as a prophylactic, but he warned against bleeding to syncope. Although he was an active bleeder, he cautioned against excessive depletion, urging that "loss of blood may become harmful, because the vital spirit flows-

*This truly great physician and philosopher was the bosom friend of Cicero and a pupil of Democritus, who really foreshadowed the "cellular theory" by teaching contrary to the prevalent humoral theory, that "not the juices of the body but its elements and atoms are active in promoting health, and that their disturbance constituted disease." The intellectual preeminence of Asclepiades is attested by Pliny.
away with it and large losses must impair all
the natural processes."

The first centuries of the Christian era, when
science and art lay prostrate, constitute
the darkest period of the history of medicine.
Amid the darkness, and the excesses com-
mited by the monks and others who arrogated
to themselves the title physician, a few true
medical spirits shone like gleams of promise.

Alexander of Tralles, living in the sixth
century, though a follower of Galen, was
courageous enough to oppose him by insist-
ing that the physician should not follow any
system of treatment, but that he should be
guided in each case by the age, constitution,
natural powers, and mode of life of the
patient. Despite these sound views, bleeding
was his chief remedy, though he cau-
tioned against the excesses which he daily
witnessed among the motley practitioners of
his day.

The fifteenth century produced that er-
ratic but clever reformer, Paracelsus, of
whom the historian Ranke has said: "In
him lived a spirit ingenious, profound, and
endowed with rare knowledge." Although his
vanity and bad habits made many enemies,
and his alchemic doctrines betray the spirit
of ignorance which was the prevailing char-
acteristic of his time, he displays true med-
ical intuition in the earnestness with which
he inveighed against Galen's doctrines and
spoliative practices, and in his recognition of
the authority of Hippocrates. He wrote:
"When disease attacks the body, all the
healthy organs must combat it, for disease
tends to kill them all. Nature recognizes this
fact, and therefore she attacks it with all her
might." What Hippocrates called "vis medi-
catris nature" Paracelsus termed the inner
alchemist." He proclaimed boldly: "Nature
is the physician, not you! Since I saw that
the doctrines of the ancients have accom-
plished nothing but the making of corpses,
death, deformity, and decay, I was compell-
ed to pursue the truth by another way." What-
ever the failings of this man, be he charlatan
or wiseacre, these ideas betray a realization
of the aims of the true physician as we re-
gard them to-day.

The same century produced Brissot, who
with great learning and logical acumen in-
culated that inflammation does not always
demand venesection, because "the powers of
nature, which always aid the diseased organ-
ism, may produce salutary congestion." He
opposed general bleeding and preferred, like
Hippocrates, local depletion. It is a sad
commentary on the spirit of the medical
profession of that day, and exemplifies
the enormous prejudice in favor of bleeding, to
record the fact that poor Brissot was not
long permitted to sing the praises of "vis
medicatrix." He was driven from Paris to
Portugal, where he died a martyr to his
excellent doctrines, amid the curses and mal-
edictions of his confrères.

In every country bleeding, purging, and
other spoliation continued the weapons with
which disease was attacked.

A reformer appeared in the seventeenth
century. Van Helmont sought to end the
sad reign of spoliative therapy which had
resulted from the perversion of the doctrines
of Hippocrates during the dark ages. De-
spite his fantastic and mystical tendencies and
practices, he was a brilliant physician, which
is evidenced by the fact that even in that
time he laid special stress upon the fallacy of treating symptoms. "Diseases
have no roots," he wrote; "their termination
is based upon the removal of their causes;
the aim of treatment should not be the cool-
ing of temperature and removing the chang-
able symptoms; the physician who directs
his chief attention to these things and not to
the removal of the cause, loses time, labor,
and opportunity." He prescribed opium as
a stimulant, and mercury, antimony, and wine
in fevers. Against depletion he strove with
might and main: "I estimate that indication
most highly which is based upon the main-
tenance of the strength; venesection is di-
rectly opposed to the latter; the entire
Treatment should be for the maintenance of
these powers. In fevers the indication for
bleeding is absent. It is forbidden that he
injure Nature, who should hasten to her aid
when she tries to help herself. She can do this
more perfectly the more vigorous she is. The
physician should certainly know that without
his interference the patient is debilitated
enough by the disease, the loss of appetite,
restlessness, pain, fear, wakefulness, and per-
spiration. By the rapid withdrawal of blood
Nature is hindered in the destruction of her
enemy. It is an insane practice to draw
blood so frequently and at the same time
offer the patient nourishment, regardless of
the complete abeyance of his digestive pow-
ners."

To us of this enlightened era these views
have the true ring; how singularly perverse
was the medical mind in refusing to accept
these salutary lessons! How steeped the
medical profession was in its errors, and how
authority ridden, is sadly evident from the fact that Harvey, the discoverer of the circulation of the blood, was so persecuted by reason of his teachings that he lost his large practice in London, and his work, being refused censorship in England, was printed in Frankfort several years later (1628). In Paris his book was also prohibited.

It required a bold spirit indeed to antagonize the prevailing doctrines and the hapless therapy based upon them.

Now appeared upon the scene the famous Sylvius (1660), who taught Van Helmont's method in the University of Leyden. He added certain chemical doctrines which seem extremely absurd at the present time. He spared the patient's vitality by refraining from depletion, his chief remedies being simple diluents. His influence was good, but it did not seriously check the bloodthirsty doctrines. The discovery of the circulation of the blood even did not bring order out of the then prevailing therapeutic chaos. The circulation was regarded as a hydraulic process, and diseases were thought to be due to a despoiling of the blood, which could be remedied by bleeding and even by injecting medicinal agents or animal blood. The holocaust to venesection continued to accumulate, and the voices of the few great reformers were silenced amid the detractions of a multitude of despoilers.

In the latter part of the seventeenth century a brilliant star arose in the medical firmament. Thomas Sydenham strove to reinstate the lost doctrines of Hippocrates and relegate Nature to her merited position as a healer. A rational empiricism, a treatment free from speculation and based entirely upon observed facts, was his aim. Sydenham defined disease as "an effort of Nature to preserve the patient; this effort is manifested either by a purifying fever, the symptoms of which are the signs of Nature's battle, or by intestinal evacuation, sweating, or cutaneous eruptions. If Nature conquers the disease becomes acute; if not it becomes chronic."

Although Sydenham, like Hippocrates, believed that it is the physician's duty to watch closely the processes of Nature in the furtherance of cure, he erred, like the great Nestor, in regarding high fever as an abnormal action, which must be modified by antiphlogistics, bleeding, purges, watery diet, and cool surroundings. He was a determined yet wary bleeder, always cautioning against excesses and deploring the therapeutic barrenness which forced him to resort to venesection, a remedy which he regarded as debilitating and destructive to the whole body. He said that "a regular system of management frequently cures many diseases better than the powder of the apothecary." He valued cinchona and opium highly. As a pupil of Locke and a student of the Montpellier school, which had served to maintain the rationalism of Hippocrates amid the chaotic confusion into which it had degenerated, he was a strict observer and insisted upon definite indications for all treatment.

Another evidence of returning good therapeutic sense is furnished by the life and teachings of one Gideon Harvey, a contemporary of Sydenham, who was physician to King Charles II. and William III., and city physician of London. He wrote a book in 1689 on "The Art of Curing Disease by Expectation," in which he violently assailed the prevailing spoliative methods. He may be regarded as the father of the expectant treatment, which came into vogue in the latter half of this century.

The enlargement of knowledge resulting from Harvey's great discovery and Sydenham's philosophic and yet practical teachings appear to have influenced therapeutics very little. We find in the writings of Pechlin (1700), who was a very conservative practitioner, the statement that spoliative methods continued in vogue in Europe and that especially in France bloodletting became a veritable fashion, against which the scathing satire of Moliere was as impotent as the eloquent warnings of the few rational physicians.

Even Boerhaave, who was justly regarded as the most celebrated physician in Europe, labored under the terrific error of spoliative therapy. Despite the fact that he recognized and warned against the devitalizing effect of depletion, he not only bled in most diseases, but recommended venesection to facilitate the absorption of medicines. He had a large following in all parts of the world. He wrote: "If we compare the good which half a dozen sons of Æsculapius have accomplished since the origin of the medical art upon the earth, with the evil which the immense mass of doctors have done among the human race, there can be no doubt that it would have been far better if there had never been a physician in the world." This sentiment, which was afterward wittily reiterated by our own Oliver Wendell Holmes, certainly reflects much truth, so far as internal medicine is concerned. The forlorn plight of therapeutics, its sad consequences for suffering humanity, cannot be depicted more eloquently.
than by this statement of the foremost physician of Europe, who was himself so enamored of the spoliative practice which he condemns that he was utterly unconscious of his own participation in it.

After figuratively wading through tales of blood-spilling, the diligent student of medical history is refreshed by the clear and rational teachings of Friedrich Hoffman, in "De naturae et artis efficacia in medendo." Inveighing against the habit of being bled, because "in the blood is contained the entire stock of vitality," he recommends a simple therapy, consisting of bland diet, cool drinks, and baths, mineral waters, milk, wine, lead, camphor, iron; and opposes the use of opium and other poisons.

A staunch defender of Nature among the multitude of bleeders was Gaub, professor at Heidelberg, who wrote the first book on pathology. He regarded Nature amply competent to remove disease, which he considered quite as natural as life or death.

Stahl is another great man who left a favorable impress upon therapy. He wrote: "Nature, the physician of diseases, offers a better prospect of curing them than the most perfect apparatus of our art." He warned against too active medication and depletion, "which suppress the completely misunderstood efforts of Nature."

In France an outspoken opponent to depletion was Borden, who dubbed the Charité "the leech bureau." He lived in the latter half of the eighteenth century in Paris, when venesection was running riot. He disregarded plethora and valiantly defended Nature. Although he used the lancet, he warned against it in fever because "bleeding shatters the constitution and disturbs the function at a time when the organism requires all its vitality for the purpose of removing the disease." "Many a broken-down constitution," he writes, "is dragging itself around burdened with chronic disease as a result of disturbance and hindrance of Nature's work by bloodletting in acute diseases. In rheumatic and catarrhal diseases especially Nature is the sole curative factor."

While a reaction against depleting methods was brought about in France by the teachings of Borden, Castellot, and others, and by the conservative doctrines emanating from the great Montpeller学校, the teachings and practice of Sydenham continued to be perverted by English physicians. Unfortunately many of them disregarded his warnings and blindly bled for all diseases.

The philosophic Cullen was an active bleeder, although, like Hippocrates, he warned against excesses; he laid down indications for drawing blood and prescribed tonics, stimulants, cinchona, wine, and opium.

Depletion still continued to sway the medical mind, however, until De Haen appeared in the latter part of the eighteenth century. A true exemplar of rational medicine, he taught that "Nature must not be disturbed by powerful medicines." He prescribed chiefly absolute diet, cooling drinks, and mild cathartics. De Haen is the founder of the Vienna school of medicine, which was destined with interruptions to endure to the present day. His beneficent teachings struck the first decided and lasting blow to spoliative methods, and gave birth to greater trust in the vital restorative powers than had ever before been embraced by medical men. Some of his immediate successors, like Stoll and Peter Frank, neglected his teaching, while his later offspring, Skoda, exaggerated it into a therapeutic nihilism. Gottlieb Vogel and Peter Frank, men of great renown, bled without stint, but warned the students against syncope, and taught that the organism should be allowed to retain sufficient vitality, so that "we may not murder with the cupping-glass those whom the disease had spared."

As an evidence that Vienna was still the center of spoliative therapeutics in the latter part of the seventeenth century, let me cite Wollstein, formerly a most zealous bleeder, who seeing the error of his ways, became a violent propogandist against venesection. He candidly admitted having nearly killed himself with it and having since his youth spilled thousands of pounds of blood. He writes: "I now look back with horror upon the twenty years of my bloody activity, by which health, animal nature, vitality, and its best weapon against disease—fever—were destroyed, a practice into which I had been decoyed by teachers and books. I know from my own experience no case in which bleeding deserves the name of a curative agent. Even in these troubles it helps only man; cattle and horses suffering in the same manner are not relieved by it. We should, we must, tremble in the application of an agent which makes weaklings of strong men and animals." Wollstein pointed out as no one before him, and until recently few succeeding him, have done, that the physician should not be deceived by occasional brief improvement of symptoms after venesection; he pleads for due regard of its evil after
effects. "If the patient survives it, destruction of body and mind are the sad consequences which the doctor will observe after a cure by the cupping-glass." The courage of his convictions aroused this simple doctor to a valiant battle with prejudices and practices which were universal. His voice, however, was too feeble to stem the tide of blood surging around him. Antagonists arose on every side and counteracted his warning.

In the last years of the eighteenth century the medical philosopher Gall exercised a favorable influence upon his contemporaries. Recognizing the natural conservative activity of the organism, he endeavored to restore that simplicity in therapeutics which had been so long lost in practice, and to show the fallacy of the view that because Nature sometimes attempted to relieve by spontaneous bleeding from the nose, hemmorhoids, etc., diseases may be prevented or cured by removing a great deal of blood. Like Hippocrates, Gall regarded bloodletting as a de-vitalizing agent, which never weakened the disease, and only acted as a palliative by freeing the natural powers when plethora existed. He weighed against these one-sided methods in acute diseases, which "by rough and forcible interference lowered the system," and warned earnestly against "those extravagant losses of blood which produce relapses and enfeeblement if they do not destroy life."

That the medical profession remained callous to the admonitions of these wise physicians is a deplorable fact, evident from the writings of that day."

The close of the eighteenth century witnessed little abatement of spoliative therapeutics. With regard to medicinal agents it may be of interest to recall the fact that while in its earlier years many absurd remedies, like mummy, wood lice, dung, were regarded as efficacious, many medicinal agents were added which are of great value. Cinchona and opium were firmly established, despite violent opposition. Dover's powder was introduced; conium, stramonium, hyoscyamus, colchicum, were investigated by Stoerck, digitalis by Withering and Darwin, potassic solutions of arsenic by Fowler, acetate of lead by Goulard, corrosive sublimate by Van Swieten; oxygen was introduced for inhalation and mineral springs were studied; the external and internal use of water was introduced by Floyer in England, and by Friedrich Hoffman in Germany. The latter recommended cold baths "to restore elasticity to the solid parts." Hahn in Germany and Currie in England introduced the modern bath treatment of fever. Electricity was also introduced as a remedial agent.

The therapeutic attitude of the better class of medical men at the dawn of the nineteenth century is evident from the writings of Reil, who had distinguished himself by advocating the abolition of the medieval maltreatment of the insane: "Bloodletting is a very effective remedy, which alone is capable of saving life in some fevers and of paving the way in others. The untimely use of venesection is injurious; simple benign fevers do not require it; only the severe grades. Nature, not bleeding, removes fever. In inflammatory pneumonia a single bleeding restores expectoration, while excessive bleeding reduces the tone so that expectoration is absent and we are compelled to resort to senega, sulphur, etc. A bottle of porter often saves a patient who would have been killed by bleeding. Excessive and untimely bloodletting disturbs resolution, retards the crisis, slows convalescence, and sometimes produces effusions of lymph into the chest, with dropsy, suffocation, and apoplexy."

*A graphic picture of the practice at that time is furnished by Metzler, who "as the son of a country surgeon often saw in one day several hundred persons assemble for bloodletting, during the Easter holidays. Without any idea of medicine I was astounded by the indifference with which entirely healthy people, as well as those weakened by age or disease, allowed one or two pounds of blood to be taken, how one after the other dragged himself away faint and trying to refresh themselves by cold sprinkling of their faces, how they often made sport of persons lying in deathlike faints, and then seated themselves and allowed their blood to flow until they too grew weak and pale, often vomiting and sinking down exhausted. This silly action of the country folk astonished me, and this fearful effect of bleeding made a deep impression on my youthful mind. The correct ideas which I formed by reflection upon them were dissipated by the teachings of my professors at the medical schools. Fortunately I soon became convinced of the narrowness of the latter, how little I learned from them, and how much I still lacked in medical knowledge. I therefore studied the ancients, threw aside the laboriously learned school knowledge, and endeavored to gather all the Hippocratic teachings as my guide. Thus I became a physician; thus I obtained my conceptions of bloodletting and found myself more content at the bedside." He relates how his practice diminished because he refused to bleed pregnant women, drunken priests, and hypochondriacal politicians. He was dismissed from the practice of one convent because he advised exercise, abstinence from priestly labors and gormandizing instead of bleeding. "I only bled when it was in accord with my principles, and I have never had cause to regret this practice. I have often assumed my views from time to time; they have been read from Slavonia to Paris. I have written of the beneficence of fever and against the thoughtless use of bleeding, and all those remedies which practitioners so constantly ply like a trade for the calming and suppression of febrile movements, which are so often useful."
Readers of medical history are familiar with the Bruonian System, promulgated by the brilliant Thomas Brown. His stimulating practice is said to have "slaughtered more human beings than the French Revolution and the wars of Napoleon." This extravagant charge is probably the anathema of his depleting contemporaries, proclaimed upon his revolutionary doctrines.

In America the depleting practice was advocated by the well known Benjamin Rush. He recognized but two types of remedies, stimulants and depressants. He called calomel the Samson of the materia medica; his opponents contended that he was right, since it had undoubtedly slain its thousands (Roswell Park). In his treatise ("Upon the Advantages which Bloodletting Offers in Many Important Diseases") Rush proves himself a valiant and ardent defender of venesection, recommending it even in infants six weeks old and in the aged. The teachings of Rush dominated American medicine for many years, practically without opposition.

Throughout the entire world the battle between the depleting and conservative practice went on, the former always represented by the great mass of physicians, the latter espoused by a few isolated spirits who displayed laudable courage in thus opposing the popular destructive treatment of disease. Among the latter was at this time Ernst Horn, who wrote (1803) that "the waste of blood should be punished just like every poisoning; indeed, physicians who permit themselves to be deceived into bleeding by real or imaginary fulness of the pulse by increase of heat, stupor, delirium, etc., should be deprived of practice."

How the same fallacious theory may form the basis of opposite modes of practice is illustrated by that interesting but fatal method of treatment of the Italian teacher, Rasori, who had become a warm advocate of the Bruonian stimulant and contrastimulant theory. He differed from Brown materially in that he regarded the latter as far more frequently indicated than the former. In an epidemic of typhus at Genoa Brown's stimulating treatment was so destructive that Rasori afterward resorted to depleting measures in most cases. He not only used vena-

*It is stated by Haerer that Marcus, a follower of Brown, "consumed in his hospital at Bamberg in one year, 1 drachm of opium, 195 grains of camphor, 529 grains cinchona, besides other medicines, for each of 367 patients." How well endowed this hospital must have been!
repeated bleedings. Dr. Frappart ordered for one patient 1800 leeches, under which the latter promptly died. These statements brought Rivière before the courts, which mulcted him in the sum of 500 francs damages and prohibited his book! During the reign of the bloodthirsty Moloch few dared to rebel against the scientific ministers of this healer (?) Rivière suffered for his temerity.

So great continued the influence of spoliative medicine that the renowned Laennec actually prescribed moderate venesection and large doses of tartar emetic in pneumonia, which proves that Laennec's therapeutic insight was not as deep as was his diagnostic skill. The latter is also evident from the fact that he attempted to create artificial sea air in the badly ventilated wards of his hospital, by scattering fresh seaweeds under the beds of his phthisical patients!

The time was now ripe for a reform! The great French school founded by Bichat gave birth to such men as Louis, Andral, and Magendie. These laid the foundation for exposing the fatal errors of Broussais and of his predecessors. Andral and Gavarret, whose blood studies were the pride of physiological text-books in my student days, opposed the spilling of blood and resorted to cathartics and emetics. Magendie, the father of modern physiology, exercised an enormous influence in favor of rational therapeutics. "Medicine," he wrote, "is nothing more than the physiology of the sick man. It is really depressing to examine the different remedies used in each disease. Let us examine how things are going in our Parisian clinics. Take a case of typhus. One practitioner treats it with purgatives, another with bleeding, a third with so-called tonics. Others, to which category I belong, allow the disease to go undisturbed through its various stages."

Nevertheless Magendie was not a therapeutist nihilist; for he investigated, with that acumen which has immortalized him, the various medicinal alkaloids, in order to obtain from animal experimentation positive results not to be obtained from crude drugs, thus conferring a lasting benefit, which we of the present day still enjoy. He assisted most efficiently in overthrowing the fatal doctrine of local phlogosis urged so brilliantly by Broussais, and he insisted that "the entire organism must be regarded in our treatment of disease. It must not be forgotten," said he, "that a pneumonia patient suffers from something else besides a diseased lung."

Louis, who sought to establish the numerical method for proving the value of remedies, published a work on pneumonia to prove the inutility of venesection, whether it was copious or moderate. "The result of my investigations," he writes, "upon venesection agrees so little with the universal opinion that I hesitate to publish it."

In England many eminent physicians gradually abandoned extreme spoliative methods in acute disease and adopted an entirely opposite treatment in chronic diseases, which they regarded as due to debility. Iron, cinchona, and other tonics were judiciously applied in connection with hygienic and dietetic measures. To the credit of English medicine be it said that the first work upon the hygienic treatment of chronic diseases was written by Sir James Clark ("On the Sanative Influence of Climate"). Thus the seed for more rational therapeutics was sown among the leading medical minds of England, while the ordinary practitioners still continued to bleed and purge and vomit their long-suffering patients.

While rational methods of treatment, based upon professedly exact pathological and chemical data, were promulgated by the greatest physicians of France and England, there appeared a reform movement in Germany—a new system, which was distinctly outspoken in its theory and diametrically opposite in practice to all former ones. I refer to homeopathy.

Hitherto the fanciful structures of the system builders were sufficiently strong to resist the incubus of venesection and depleting measures, which like a great ogre sat upon and overshadowed them all.

The voices which now and then were raised against these spoliative methods, though earnest and soul-stirring, proved too feeble amid the general acclaim for depletion. We are too familiar with the eccentricities of Hahnemann, which have been long inveighed against by many earnest physicians (called by his followers allopaths). And yet when we compare the crudities of Hahnemann with the fatal doctrines which have weighed like a nightmare upon the practices of our own predecessors, we may discern very little if any cause for the diatribes that have been launched against homeopathy. I am free to confess that medicine really is indebted to Hahnemann for having dared to set his face against the universal and fatal spoliative practice which dominated the entire medical world and oppressed even the
most judicial minds. As you know, he depended entirely upon infinitesimal doses, whose inertness the following example shows. He writes: "When lycopodium is treated in the manner homeopathic art develops crude drugs, and one grain is brought by means of triple trituration of one hour, each time with 100 grains of milk-sugar, to the millionth dilution and potency, a remedy of such wonderful activity is produced that one grain of it dissolved in 100 drops of dilute alcohol and twice shaken in the hands, results in a fluid which in the smallest possible dose is still too active in the disease for which it is appropriate. Not until the potentized sextillionth dilution is produced does the drug begin to be useful."

Such positively inert medication, to which he wisely added good dietetic and hygienic management, surely left the vis medica\textit{tris} full sway, and right royally did Dame Nature assert herself. Hahnemann thus became unwittingly the creator of an epoch in medicine, to which may be traced the reinstatement of the doctrines of Hippocrates and Erisistratus, untrammeled by the anatomical and physiological obscurity of their day.

(To be continued)

THE EMPLOYMENT OF THE KALT SUTURE IN CRITICAL CASES OF CATARACT EXTRACTION.*

BY S. D. Risley, A.M., M.D., PHILADELPHIA, PA.

Attending Surgeon, Wills Eye Hospital; Professor of Diseases of the Eye, Philadelphia Polyclinic, and College for Graduates in Medicine.

While in Paris in 1894 I had the opportunity to see Dr. Kalt of that city insert the corneoscleral suture devised by him in six cases of cataract extraction. His claim was that it diminished the percentage of iris prolapse after simple extraction.

The suture was introduced before the corneal section was made, and the lips of the wound drawn firmly together after the delivery of the lens and the toilet of the eye had been effected. The suture is introduced in the following manner: A short, sharp needle, curved on a short radius and without a cutting edge, is made to enter the clear cornea about 2½ millimeters from the limbus, penetrating behind the anterior limiting membrane and well into the corneal substance proper, but not entering the anterior chamber.

* Read before the Ophthalmic Section of the College of Physicians of Philadelphia, April, 1899.
apparently in the capsule which remained in the eye, the lens evidently escaping through a rupture in its lower periphery. The ends of the suture were then slowly drawn upon, shortening the loop and approximating gradually the lips of the wound over the prolapsed vitreous, which slowly returned within the eye. The suture was then tied firmly, bringing the edges of the wound into apposition, and the eye was closed without loss of vitreous.

The recovery was without accident, and pursued an entirely normal course. The stitch was washed away during the dressing about the fifth day. The result was $V. = \frac{4}{3}$. It is possible that the vitreous in this case might have been replaced by other means, or it might have returned after a few moments of rest with the lids closed, but the danger of infection would have been greater, and I have not been equally successful by other methods in cases of prolapse of the vitreous. The sense of security afforded to the surgeon by the presence of the suture is very great under circumstances where a loss of fortitude by the patient might lead to a complete emptying of the ball. One objection to the presence of the suture is the possible increased danger of infection of the cornea at the points of its insertion and exit; but this was not even threatened in either case here reported, and the danger probably finds compensation even in this respect by the rapid closure of the corneal section.

Case II. — Mr. M., aged forty-one; private patient. Had always had defective eyes, but consulted me on June 26, 1894, for progressive failure of vision, postocular pain, and undue sensibility to light. He had a shallow anterior chamber on each side, and pupils were not larger than an ordinary pin's head. The irides were tremulous, O. D. V. = \frac{4}{5} / \text{min}, O. S. V. = \frac{4}{5} / \text{min}, and he was able to read D. = 1 at about twenty-five centimeters. There was no range of accommodation. He had never worn glasses. The pupils under cocaine and atropine dilated to about 2½ millimeters. Ophthalmoscopic examination of the fundus oculi was unsatisfactory, owing to the small diameter of the pupils. The ophthalmometer indicated an astigmatism in O. D. = 5.00 D. axis of correcting cylinder 105°, and he selected $+1.00 + 5.00^\circ \text{ax} 105^\circ V. = \frac{4}{5};$ O. S. = 5.00 D. axis of correcting cylinder 75°, and he selected $+1.50 + 5.00^\circ \text{ax} 75^\circ V. = \frac{4}{5}$. He received these glasses for constant wear and enjoyed complete relief from the postocular pain, and dread of light. One year later he selected a stronger spherical glass for each eye, the cylinders remaining unchanged, and vision rose to most letters in $\frac{4}{5}$. In January, 1896, he returned with a cataractous lens on the left side, which he said had come on within a few weeks while absent from home, and had been preceded by a return of the postocular pain and dread of light. These symptoms disappeared as soon as he was no longer able to see with the left eye. He had but little difficulty, following the loss of vision in O. S., until August, 1897, when vision began to fail in O. D. from commencing opacity of the lens, the opacification beginning in the upper and outer quadrant, instead of the lower and inner, as is usual. A preliminary iridectomy was then advised for the left eye, and performed on October 26, 1897. The operation was smooth, and the eye recovered without accident, although convalescence was more protracted than usual, and he had frequent photopsies.

A month later extraction of the lens was attempted and was attended with much loss of vitreous and a protracted convalescence, but $V. = 20-64$ with $+1.25 + 1.50^\circ \text{ax} 105^\circ$, the ophthalmometer showing As. = 1.50 D. axis of correcting cylinder 105°. It is interesting to note the surprising change which had taken place in the corneal radius. Before operation there was 5.00 D. of astigmatism with the rule — i.e., at 105°. After extraction this had disappeared, and the longer radius was at right angles to its former position. As. = 1.50 D., so that a change of curvature amounting in all to 6.50 D., as expressed in the value of the correcting glass, had taken place in the process of healing.

April 4, 1898, a preliminary iridectomy was done on the right eye, and the following October the extraction of the lens. In view of the experience with the left eye the Kalt stitch was introduced. The section was then made, and was followed promptly by a large protrusion of a semifluid vitreous, and the lens was delivered with the loop as in the other eye, leaving some opaque cortex within the eye apparently enclosed in the vitreous, which filled the anterior chamber and protruded through the wound. No attempt was made to remove the remnants of cortex. The ends of the suture were then slowly drawn upon; the protruding vitreous promptly receded, and the lips of the wound were forced into apposition. No vitreous had to be excised. The wound healed promptly and con-
valescence was rapid, so that the patient was discharged from his room in the Polyclinic Hospital in two weeks from the date of operation. A capsulotomy was necessary a few weeks later, after which vision rose to 6-XX with + 14. C + 2.50° axis 100°. The ophthalmometer indicated 2.50 D. of astigmatism, axis of correcting cylinder at 100°. It will be observed therefore that the prompt healing of the wound made possible by the stitch avoided the marked change in the curvature of the cornea witnessed in the first eye. There a change of 6.50 D. followed the operation, but in the second eye of only 2.50 D.

Case III.—Female, aged fifty-two. Sent to me at the Willis Eye Hospital by Dr. E. A. Gearhart, of Allentown, Pa., on February 3, 1899. O. D. blind; O. S. counted fingers with much difficulty in upper and outer field, but was unable to go about alone. The eyes were white, T. = n. There was a broad peripheral coloboma at the inner and lower quadrant of the iris in both eyes, and the lenses were opaque. In the left the iris was tremulous, and a wave could be seen in the anterior chamber with every movement of the eye. The suspensory ligament was ruptured. She was free from pain. She had been under the care of Dr. D. Hall at the hospital, and presented the card received at that time. The old record was consulted, when it was found that she had been admitted to the hospital with syphilitic iritis on October 7, 1886. She was then blind in the right eye, and the lense was cataractous. The state of the vision in the left eye is not noted. There was annular synecchia in both, for which double iridectomy was done at the same sitting on October 12, 1886. After leaving the hospital she relates that the vision improved in the left eye so that she was able to see her way about her own house until seven years ago, when she was struck in the eye with a stick, since which time she has been helpless. She was extremely solicitous lest she might lose her small modicum of vision still retained, but finally consented to an operation. Profound general anesthesia was secured, and with the aid of my assistant, Dr. Thorton, and the house surgeon, Dr. Ford, the Kel suture was introduced as in Cases I and II, and a section made parallel with the base of the coloboma in the corneal limbus. A large mass of vitreous immediately presented. The wire loop bent into a spoon shape was then inserted, gently pressing the protruding vitreous backward, and carried well behind the lens, embracing its posterior surface in the concavity of the loop. The lens was delivered without difficulty, its exit being aided by following its movement outward by pressure through the cornea with a horn spatula. The lens was extracted in its capsule and left a clear black pupil. The suture was then drawn upon as in Cases I and II. As the lips of the wound approached, the protruding vitreous slowly returned within the wound, except a small bead at the outer angle, which was excised. The edges of the corneal section were gently stroked into close and smooth coaptation, and the suture firmly tied. The eye was closed, a cross of isinglass plaster placed over the lids, and a cotton pad and bandage applied. The eye recovered without reaction. There was slight bulging of the wound at the outer angle on the third day, where the vitreous had been excised, but the anterior chamber was restored, and the patient was able to count fingers in candle-light. The stitch was removed on the seventh day, and the patient allowed to get out of bed. There had been no evidence of infection around the threads at any time. On the tenth day the eye was quiet and rapidly losing its injection. A minute scar could be seen in the cornea at the site of the suture, but was larger and much more conspicuous at the scleral portion of the stitch. The anterior chamber was of normal depth, and the cornea showed no distortion. The wound was smooth and flat throughout its entire extent, and the pupil clear and black. Patient is greatly pleased over her improved sight, but no letters can be made out.

Cutaneous Burns and Their Treatment.*

By Ellice M. Alger, M.D.,
Lecturer in Dermatology at the New York Polyclinic; Attending Physician, Demitl Dispensary.

Technically a cutaneous burn may be defined as an inflammation of the skin produced by heat, but clinically those inflammatory conditions caused by the sun and by electricity must be included, though the heat produced by them is not the principal factor in all cases. The earliest classification of burns was that of the celebrated Dupuytren, who divided all burns into six degrees according to the extent of the tissue destruction, but there has been a growing tendency

* Read before the New York Medical Union, March 28, 1899.
to simplify this classification, and Rayer's modification of it has come into general use. This extends only to three degrees, the first including all burns characterized by simple reddening of the skin, without vesication, the second those in which vesicles or blebs form but without doing permanent harm to the skin, and the third those in which enough tissue is destroyed to cause the formation of scars.

Theoretically burns of each degree should present characteristic features, both clinically and microscopically, but in actual practice we not infrequently find lesions of all three degrees in the same case, while very often lesions of the first and second degrees are changed by the invasion of bacteria into lesions of the second and third. Burns of the first are often trifling affairs, but when extensive may be productive of much discomfort and even constitutional disturbance. The skin becomes decidedly red and swollen, presenting an appearance not unlike that of erysipelas without its sharp definition; pressure momentarily drives the blood away, leaving a dirty, yellowish stain, and when the pressure is removed the blood flows back very slowly. In the course of a few hours or days the redness is gradually obscured by thickening of the epidermis, the swelling gradually disappears, and a process of exfoliation continues until the skin is again normal in thickness.

Clinically burns of the first degree, whether produced by dry or moist heat or by the sun, present about the same appearance, but pathologically they are very different.

A sunburn is not at all dependent on the production of heat, for it is especially marked in certain skins exposed to the action of sunlight reflected from water and snow and ice, even though the temperature may be many degrees below zero. A burn of this kind is probably due to the action of the violet rays of the spectrum on skins predisposed to the process. Presumably the actinic rays exert a chemotactic action capable not only of causing the development of pigment in the skin, but when long continued, of producing true inflammation and exudation. The pigment is supposed to be formed from disintegrated red blood cells.

Burns of the first degree which proceed from the direct application of heat are much better understood. The first effect of intense heat on the skin is the stretching of the horny layer, which when the heat is dry remains stretched and loses its elasticity. This is very well shown by the little horny ridges that follow the light application of the Paquelin cautery to the skin in lumbago. In the living subject the usual changes comprised by the word inflammation begin at once and last a varying time, but as no essential part of the skin has been destroyed no permanent damage to its integrity results. In the way of treatment the only indications are to relieve pain and to hasten the exfoliation of dead skin, both of which are met by the application of a five-per-cent watery solution of ichthyol to which a little starch and albumen have been added.

In burns of the second degree the skin is at first considerably reddened, and within a short time vesicles appear, large or small, flaccid or tense. Many vesicles discharge their contents, and only tags and shreds remain. Their size varies greatly and depends largely on the thickness of the skin, those over thin areas becoming very large and rupturing early, while those in thicker locations appear much later and are smaller in size. Eventually the blebs break and suppurate if left alone, or dry down and form crusts and scales, which drop off. Very naturally burns of the second degree, if extensive, may be productive of great agony and shock.

Pathologically, the first effect of the heat is the stretching of the horny layer, which remains, if the heat has been dry, somewhat raised and inelastic. At the same time there is not infrequently, if the heat has been intense, enough steam developed from the moisture in the tissues to cause an instantaneous appearance of small vesicles; but the formation of true burn vesicles and bullae is a later and entirely different manifestation. Here there is an evident distinction between the action of moist and dry heat. In the dry burn the horny layer remains permanently stretched and appears loose, and as a result the exudation, even if it be slight, is distributed pretty evenly under its cover because of the lack of outside pressure. In the moist burn, while the cover is stretched by the heat it retains its elasticity and at once regains its shape. As a result, when exudation does occur the size and shape of the bullae depend entirely on the amount of fluid, first appearing in the center, where pressure is least, and spreading gradually toward the margin, where pressure is greatest.

In a dry burn we may find a good many flaccid bullae, because the horny layer is stretched over a large area, but the burn
being superficial, not enough fluid is produced to make the bullae tense. Therefore the bullae in a dry burn tend to be flat-topped. In the scald, on the other hand, the elastic vesical wall fits closely over the fluid, be it great or little, and the vesicles are tense and tend to assume a dome shape. The amount of exudation seems to depend on the extent of damage done the prickle cell layer, and is regarded as due to chemotaxis following the death of tissue.

The inflammatory process is greater than in primary burns, but no essential structure is destroyed and no scar follows.

The indications for treatment in such burns are three: first, to relieve pain, which is always intense; secondly, to prevent infection, which is certain to produce cosmetic defects, and may cause grave constitutional disturbance; and thirdly, to hasten repair by increasing cornification. For relief of pain immersion in water is one of the oldest and most successful methods, but it must in most cases be a temporary expedient, for a wet dressing does not by any means answer the same purpose. In those extensive burns where life itself is in danger there is no treatment to compare with it. The patient lies day and night in a tub of running water, which is kept at about the body temperature and may be medicated if desired. By the constant flow of water air is kept from the surface and good drainage assured. Repair is somewhat hindered by the constant soaking, but the keeping the patient in comfort till all danger of shock is past is of far more importance.

In milder cases the application of carron oil (equal parts linseed oil and lime-water) has been for years a popular dressing, and if some antiseptic be used with it every indication is met; however, it is an ill-smelling, disagreeable dressing. When healing has progressed somewhat further it can be replaced by any soft antiseptic ointment like carbolized vaselin or aristol ointment. Cocaine solutions are never essential.

In all cases of burns beyond the first degree antisepsis should be carefully maintained, and in this connection it should be remembered that absorption occurs very readily from a burned surface. For this reason antiseptics such as carbolic acid and bichloride should be used in very weak solution and never applied as permanent wet dressings. A one-per-cent creolin solution makes a very serviceable antiseptic devoid of toxic properties, but boric acid and borax are the best drugs of their kind to use. Formalin in my experience has proven very irritating.

For the last two years I have been using a solution of picric acid, not only on burns of the second degree, but on other cutaneous affections attended by the formation of vesicles, and with very satisfactory results. It is a yellowish, crystalline powder, produced by the action of nitric acid on phenol, and is freely soluble in alcohol and less so in water. It is a good antiseptic and oxidizing agent, and has of late years been considered one of the best reagents for detecting albumin in urine. It is not by any means a new drug, but has lately been taken up by the French school of dermatologists, who recommend its use in aqueous solutions of from two to five per cent. It can be used in primary burns, for it relieves the pain almost at once and promotes cornification and exfoliation to a considerable degree; but it has the disadvantage of staining the skin a bright yellow, which in many cases might outweigh its advantages. Accidentally I found that the combination of picric and citric acids, which Esbach long ago devised for the detection of albumin, was more effective than the picric acid alone.

Esbach's solution consists of 10 parts of picric acid, 20 of citric acid, and 1000 of water. Without any elaborate attempts at antisepsis the bullae and vesicles should be opened with a clean blade and the fluid applied freely, care being taken that the solution reaches the interior of each one. Picric acid is rather a weak acid and coagulates albumin poorly in an alkaline medium. The citric acid acidulates the alkaline contents of the vesicles, which the picric acid promptly converts into an antiseptic coagulum capable of resisting infection and excluding the air. The combination after the first smart has passed removes the pain more quickly and completely than anything I have ever tried. After the excess of fluid has drained off the part may be covered with rubber tissue or soft gauze and left undisturbed for several days. It makes a clean and comfortable dressing, and I have never observed any toxic effects, though I have several times used it over quite large surfaces. Two cases of poisoning by picric-acid have come to my notice, but in both six ounces of ten-per-cent ointment were used over extensive surfaces in very young children; the symptoms being very like those from carbolic acid poisoning.
After two or three days the fluid should be reapplied to such areas as are moist and the part carefully recovered.

In burns of the third degree the color of the dead skin is apt to vary very much in different cases. Sometimes it is ivory white with the course of the blood-vessels marked by brownish lines; in other cases the whole skin may be brown or even black. It is dry and hard and devoid of sensation. Many times it is impossible to estimate the extent of the damage, but after a few days the dead tissues begin to separate from the living, and after the usual process of suppuration the slough comes away and scar tissue forms. When such a burn becomes infected and suppurates freely the stench is frightful. In a good many cases the deeper lying portions of the skin, like the glandular appendages and hair follicles, are not entirely destroyed, and forming centers for epithelial cell proliferation, lessen the amount of scarring. The process of repair is naturally much slower than in burns of the second degree. The variation in color of the dead skin is perhaps susceptible of this explanation. When the skin is subjected to moist heat of a high degree for some time it is converted into a gelatinous mass, white in color, while the blood in the vessels becomes a dirty brown; on the other hand, when dry heat is continuously applied the skin first becomes gelatinous and white from being steamed in its own juices, and afterward brown when it is burned to a condition of dryness, and finally black when carbonization has taken place. Burns of the third degree often produce very extensive scars, the after contraction of which may cause serious deformity. The pain is not a marked feature at first, for the whole skin with its nerve terminals is dead, but after the dead tissue has separated the granulations are often exquisitely sensitive.

The treatment must be largely confined to the limitation of suppuration and scar formation. The separation of sloughs is hastened by wet dressings of boric acid, and the formation of healthy granulation is aided by applications of balsam of Peru or silver nitrate. In extensive burns, or where a scar would cause deformity or disability, skin-grafting after the method of Thiersch should be done.

I cannot lay claim to any extended experience in skin-grafting, and speak of the subject largely for the purpose of obtaining information from others who may discuss it. It seems like a simple enough procedure.

The grafts are cut with a razor from the skin of the same patient or another under general anesthesia or infiltration anesthesia with a weak cocaine solution, planted at once on the healthy granulations, and afterward covered with rubber protective and not disturbed for several days. If the grafts are put close together and take nicely suppuration stops; if they are separate, each one acts as a center of cell proliferation, and the intervening space, if not too great, is finally covered.

As regards antiseptic precautions, the granulating surface suppurates freely, and I presume it is a practical impossibility to secure absolute asepsis. I have used at different times peroxide and boric acid and salt solution and plain boiled water for purposes of cleanliness, and the grafts took about equally well in all. Of course, the skin from which the grafts are cut should be sterilized, and any solution which could interfere with union on either graft or granulation should be washed off with salt solution.

As regards the thickness of the grafts, some of the books say the thicker the grafts the more the result looks like normal skin, and I have heard men of some experience say the thinner the grafts the better they take. In my own experience it seemed that the grafts of the thickness of tissue-paper took equally well and formed as satisfactory cuticle, while of the thicker ones only the lower layers of cells remained adherent to the granulations, the upper ones generally coming away at the first dressing. I have once or twice used grafts from a second individual, and it has not seemed to me that they took as well as those from the same patient, but this may not be the common experience.

The prognosis in burns of all degrees depends more on the condition of the patient and the extent of the burn than on its depth. As a general rule burns involving one-third to one-half the cutaneous surface are said to prove fatal in from eighteen to forty-eight hours. The cause of death is a matter of dispute to this day. According to Von Loe-scher death is the result of an acute oligocythe-mia following the destruction of red cells and accompanied by a fall of temperature from lack of oxygen and nutrition in the tissues. Lustgarten lays it to putamine poisoning, and others have ascribed it to the destruction of sweat glands producing a condition analogous to that of the varnished animal. According to Silberman thrombi formed from disintegrated blood cells are
deposited in the pulmonary artery, thus causing a venous stasis and accounting for the congestion of internal organs, the dyspnea, cyanosis, anuria, and coma. Perforating ulcer of the duodenum occurs as late as the tenth day, leaving a clearly cut opening very suggestive of embolism. Erichsen, perhaps conveying as much definite information as the rest, pronounced shock to be the cause of death.

It remains to say a word regarding burns by electricity, which are very frequent now that so many individuals have to do with its production and use. So far as I have been able to ascertain there has so far been placed on record no careful study of the nature and pathology of this variety of burn, and while I have personally seen quite a number of cases I would not venture to discuss a condition which depends on so many varying factors.

Clinically, electrical burns may present symptoms of either of the three degrees, but microscopically they will probably be found to differ in a good many points, owing to the effects of the strong currents on cell life aside from the actual heat developed. The heat effects are probably mostly shown upon the skin, for electricity develops heat only when the resistance to its progress is great, and it is a well known fact that in the skin this resistance is very great, while in the other tissues it is very slight. Conversely, the other effects of electricity are more likely to show themselves in the subcutaneous tissues, for the current tends to travel along the path of least resistance. Theoretically, the severity and extent of the burn should depend to some degree upon the condition of the skin, whether dry or moist, for an abundance of salt containing sweat would lessen the resistance and with it the heat produced. In electrocutions I am informed that when the electrodes are properly moistened so that the skin resistance is eliminated, death ensues without any burning, and it may be this factor of skin resistance which would explain the harmless passage through the body of currents usually sufficient to cause death.

Owing to the secondary effect of the current on tissues not actually burned, it is almost impossible to forecast the result of electrical burns, but it is almost certain to be worse than any other variety. In my experience, which coincides with that of others, even if the tissues do not slough the process of repair is very slow and the prognosis should be very guarded.

THE TREATMENT OF CROUPOUS PNEUMONIA WITH HOT-WATER BAGS.

The Maryland Medical Journal of March 25, 1899, has in it an article by Kolipinski on this theme. He thinks that as soon as croupous pneumonia is diagnosed, the treatment should be as follows: A pair of hot-water bags are selected, the largest size found in the shops, preferably of the capacity of a gallon. These are filled with boiling water, well secured from leakage, and each one wrapped in a small shawl of compact texture or in a portion of blanket cut for the purpose. They are then placed side by side on the bed so that the mouths of the bags point upwards; over them is placed a third shawl folded several times, or a further piece of blanket; above them two or possibly three pillows are arranged for the patient's head. The bags thus form a sort of shallow cradle for the postcapular regions. To make the plan clear to the attendant he is told that the bags must be placed like a knapsack on the back of a soldier and a little higher up as well. The bags are refilled every three or four hours. The exterior temperature, found by placing a common atmospheric thermometer between the coverings of the bags and the patient, varies from 95° to 130° F. A mean temperature of 110° F. should be aimed at, as an elevation of 120° F. or more is liable to inflict severe burns on the skin, particularly so if the patient's cutaneous sensibility is for the time obtunded. These burns, which Dr. Kolipinski says he has frequently met with, due to the overzeal or excitability of the attendants, have no untoward effect in the course of the lung fever, but very probably the opposite, and a pneumonia may disappear in a day or two when this accident has happened, although the injury itself may remain for two or three weeks.

The bag treatment is continued without intermission until the body temperature returns to normal and remains so for a day or two.

THE TREATMENT OF ACUTE RHEUMATISM BY METHYLENE BLUE.

Lemoine has reported to La Presse Médicale of February 1, 1899, his employment of methylene blue in acute articular rheumatism, and claims to produce results which are equal to those produced by salicylate of sodium. It also acts well in gonorrhreal rheumatism. He states it is essential that the blue which is employed shall be free from contamination by zinc.

DANGER IN DRUGS OF UNKNOWN POWER.

In the May issue of the Therapeutic Gazette, under the head of "Notes and Queries," will be found the call issued by the President of the Convention for a revision of the Pharmacopia.

We have already, in earlier issues of the Gazette, urged that in the new revision care be taken to exclude useless drugs, that a dose list of approximate minimum and maximum quantities be introduced, and far more important than all, that whenever possible drugs should be standardized by careful chemical assay, or where this is impossible, by physiological test.

It has always seemed to us that medical men were contented to a large degree to carry out the cynical statement of the man who remarked that "physicians were persons who poured drugs of which they knew little into the bodies of patients of which they knew less," and there is scarcely a physician who, after studying his case with the greatest skill and with the aid of all possible modern appliances, will not be careless enough to prescribe a tincture, fluid extract, or other preparation of some active substance, upon which the life of the patient and his reputation may depend, without making any investigation as to whether the pharmacopoeial product which is dispensed is capable of producing the results which a standard preparation should produce.

The writer of this editorial very frequently sees in consultation cases in which physicians have administered digitalis in varying doses with disappointing results, either because the drug has failed to do good through inherent weakness, or else because it has been so unduly strong that ordinary doses have produced such distinct physiological symptoms as almost to amount to conditions of mild poisoning, and when a properly standardized and physiological preparation of digitalis is substituted the results at first sought are promptly obtained.

It has been stated that chemical analysis and physiological testing are not practicable, in that it is impossible for the ordinary druggist who prepares his galenical preparations to go to the expense of time and labor in making these tests. It seems to us that this argument is so fallacious as to be actually dangerous.

When physicians employ chemical compounds in medicine they are careful to see that these compounds are made by manufacturing chemists whose ability and reputation guarantee that the proportions of the various ingredients are chemically correct, and any physician or druggist who was careless enough to dispense a chemical compound in which the proportions were faulty, and who failed to produce good results, would certainly be considered criminally negligent. In other words, we have come to a recognition of the fact that large chemical firms are enabled to employ skilled and trained assistants, under whose supervision only accurately compounded substances can be issued. Surely in the case of vegetable substances, which constantly differ in their strength, equally carefully trained directors should be constantly at work to standardize their products.

Every farmer knows that his crop of oats and wheat will vary with the condition of the soil and the amount of rain and sunlight to which it is exposed, and if he is intelligent he will also know that the various active food ingredients in the oats and wheat will vary according to whether his crop is exposed to
favorable or unfavorable conditions; yet the physician, who as a rule has far better mental training, fails to recognize that the medicinal ingredients of digitalis and all the other important vegetable drugs are subject to the same influence as ordinary food products, and yet he is content to employ digitalis leaves which grew he knows not where and under circumstances which in some cases may have made them inordinately powerful and in other instances practically devoid of medicinal ability.

In our struggle with disease we are sufficiently handicapped by the fact that man is mortal and that our knowledge is limited, without in addition adding to the difficulties by the employment of uncertain products when accurate ones can be readily obtained.

Three important drugs have already been standardized under the action of the last committee on revision. Let the good work go on, and let the convention of 1900 mark an epoch in the history of American Pharmacy and Medicine by the changes that we have suggested.

THE RATIONAL TREATMENT OF PNEUMONIA.

In this issue of the Therapeutic Gazette is an interesting article by Dr. Elsner, of Syracuse, upon this question, and in it he emphasizes several points which we believe to be of vital importance in the treatment of this malady. The most important, however, is the fact which he mentions, namely, that in this disease we find almost constantly marked relaxation of the blood-vessels, whereby the normal resistance of the action of the heart is removed and it pumps futilely in an effort to fill blood-vessels which are so widely dilated that there is not enough blood in the body to supply them.

It will be noticed that in one place he inveighs against the common use of nitroglycerin in these diseases, and points out that experimental study has shown that the toxins of pneumonia cause vasomotor relaxation or paralysis, a condition which is produced by all the nitrates, and therefore the administration of nitroglycerin simply increases the difficulty under which the patient is laboring.

It seems to us that this point is well taken. While on the one hand we recognize that at times in the course of pneumonia the heart may be relieved by lowering arterial tension by the use of this drug, on the other hand, taking the course of the disease as it usually occurs, such treatment is not usually necessary. The methods which Dr. Elsner advises for the purpose of overcoming these conditions of vasomotor relaxation are all of them wise, but there is one which we have been in the habit of employing with the greatest possible satisfaction and which he does not emphasize, namely, the use of belladonna or atropine, often combined with small doses of digitalis, as for example five minims of a tincture of digitalis made by diluting "normal liquid" digitalis with alcohol until its strength represents that of the tincture, given every six hours, and five to ten minims of tincture of belladonna every three hours; or if the condition of the heart is exceedingly pressing and the blood paths are relaxed, the skin being moist and covered with a clammy sweat, we immediately administer hypodermically $\frac{1}{12}$ or $\frac{1}{18}$ of a grain of atropine sulphate and $\frac{1}{4}$ grain of strychnine to bridge the patient over his crisis until the drugs administered by the mouth have an opportunity to act.

We are glad to find that Dr. Elsner holds the views that he does, for these have been our views for a number of years, and we have again and again reiterated our opinion that physicians are too apt to ignore the condition of the blood-vessels in the treatment of acute disease, and concentrate their attention upon the heart muscle itself.

The readers of the Therapeutic Gazette may perhaps remember an article by the writer upon the "Vasomotor System as a Factor in Disease," which was published some years ago, and also that we have drawn attention to the importance of this part of the circulatory apparatus in an editorial more than once.

---

THE TREATMENT OF INTESTINAL PERFORATION IN TYPHOID FEVER.

Another article in this number, which seems to us worthy of editorial comment, is that of Dr. Taylor upon this subject. We have during the last eighteen months published in the editorial and progress columns of the Gazette a number of contributions in regard to this very important question, and it will be remembered that professional opinion is more and more in favor of operative interference in this dreadful complication of typhoid fever, which is fatal in nearly every case unless the surgeon can give relief. Even when it is possible for him to operate, the mortality is
still very high, but the percentage of cases which have been saved makes it well worth while to do abdominal section in nearly every instance, not only because cases which were apparently hopeless have been saved, but also because even in patients who were apparently at death's door the operative interference, followed by washing out of the abdominal cavity with normal saline solution, has caused them to rally and frequently to recover.

The two most important questions in connection with this subject, after deciding that operative interference is wise, are, first, as to the diagnosis of the condition, and second, as to when operation should be performed. While the text-books may seem to indicate that a diagnosis of intestinal perforation in typhoid fever is a simple matter, those who have had most experience know it is not easy, and that at times it is exceedingly difficult. As is pointed out in the writer's recent monograph upon "The Medical Complications and Sequelae of Typhoid Fever," other conditions than actual perforation may cause violent abdominal pain and symptoms of collapse. Peritonitis may arise from infection of the peritoneum through the intestinal wall, before it is perforated; the rupture of a mesenteric gland, which has undergone suppuration, may produce similar symptoms; and more than all, it is important to remember that a certain proportion of cases of perforation occur in which pain is very moderate or entirely absent.

A very important diagnostic aid in determining the fact that the abdominal pain or disturbance is due to an acute inflammatory process in the peritoneal cavity is an examination of the blood. It is a well known fact that the leucocytes are not increased in typhoid fever as they are in other infectious diseases, unless some acute inflammatory complication arises, and therefore, if in association with marked abdominal symptoms leucocytosis develops, we at least have reason to believe that an inflammatory complication has arisen, although leucocytosis by no means proves that perforation itself has occurred.

The experience of some practitioners, notably that of Dr. Cushing, indicates that in cases in which there is a good deal of abdominal discomfort and pain, and in which perforation is imminent by reason of the near approach of the ulcerating process to the peritoneal covering of the intestine, leucocytosis may occur in what has been called the preperforative stage, and that if leucocytosis is very marked and rapidly increases, ab-

dominal section as a preventive measure is perhaps justified. These studies are very suggestive, although as yet it does not seem possible to rely on them absolutely.

---

**THE TREATMENT OF SOFT CHANCRES.**

The term soft chancre, or chancre, is one commonly applied to all venereal lesions which are not syphilitic—i.e., to herpes, severe balanoposthitis, infected abrasions, and a large number of genital lesions, which under simple treatment by ordinary cleansing applications heal in a few days, or at most in one or two weeks. The researches of Unna, Ducrey, Kretting, Peterson, and a host of others have, however, proven as conclusively as is possible, in the absence of inoculation from pure cultures grown on artificial media, that a chancre is a distinct entity, dependent upon a specific strepto-bacillus, of characteristic form, size, and grouping. Moreover, it is well known to clinicians that while the ordinary infected trauma of the genitalia heals in a short time under any simple treatment, chancre undergoes a period of evolution and extension for a period of three or four weeks, in spite of the most careful and persistent application of mild cleansing medicaments, after which it gradually heals; when the lesion is placed about the frenum, if it has once attained headway, a period of from four to eight weeks is likely to elapse before it is completely cured. In other words, the virus of a true chancre, though little affected by mild local applications, is finally rendered inert by the tissue resistance of the body; and providing this is fairly strong, the bacilli are so acted upon that they are not capable of further multiplication at or about their seat of inoculation, nor can they be inoculated successfully to another part of the body, nor to another person.

These facts being true, the question of aborting a chancre—i.e., of destroying the virus before it has penetrated into the tissues so deeply that it cannot be reached by germicides—becomes of prime importance. It is interesting to note that Horovitz, in a recent contribution on the subject of chancre (Centralblatt für die Gesammte Therapie, April, 1899), states that abortion is not possible, basing his belief on the well known fact that a chancre has no distinct period of incubation, but may develop in a few hours. He advises, however, where it is practicable, that the chancre should be seized in tooth-
forceps and cut out by a snip of the scissors; this operation being preceded by a thorough cleansing of the surrounding parts, and the incision being carried wide of the disease. The resulting wound is closed by suture.

The experience of the majority of surgeons who have attempted this method of procedure in any considerable number of cases is to the effect that chancroidal infection of the resulting wound is extremely likely to occur, resulting in a much larger and more serious lesion than that for the relief of which the primary operation was attempted. The destruction of the sore in its early stages by chemical applications, such as pure carbolic acid or nitric acid, Horovitz utterly rejects. In this again he differs widely from American practitioners. Clinical experience has demonstrated conclusively that in their early stages the vast majority of chancroids can be painlessly and totally deprived of their specific properties by the application of a strong solution of cocaine, followed by thorough impregnation with pure carbolic acid. This should, however, be followed in turn by a thorough cleansing of the entire region about the sore, and the application of a dressing kept wet with a mildly antiseptic lotion.

In preference to any attempt at operative treatment, Horovitz advises a thorough cleansing of the region affected by the sore with a sublimate solution 1:3000, or carbolic solution 1:20. The ulcer is then covered with iodoform powder or iodoform gauze, over which is placed cotton soaked in a five-per-cent solution of carbolic acid; over this is placed an air-tight bandage, which is left on for two or three days. This air-tight bandage seems to have for its main object the confining of the disagreeable odor of iodoform. Airol is suggested as a substitute for iodoform. The author notes that edematous swelling often follows this dressing.

Theoretically it would seem to be almost as pernicious a means of treating chancroid as could possibly be devised. A single application of a five-per-cent carbolic acid solution to the sensitive skin of the genitalia is even in itself enough to cause an edema which offers most favoring conditions for the rapid and dangerous spreading of a chancroid. All dusting powders are to be avoided, excepting in the late stages of the disease, when the specific nature of the infection has been lost, because by forming a crust, and retaining secretion, they act as powerful favoring factors in the production of bubo. Moreover, any dressing which is left on three days would, in addition to favoring this complication, encourage an inflammation of the surrounding parts by decomposition of the retained secretion.

The most successful treatment of chancroid, when the period for attempting abortive treatment has passed by, or when this has failed, is by frequently repeated cleansing and the application of gauze or cotton soaked in a mild antiseptic lotion, such as lead-water, blackwash, creolin, or very dilute bichloride of mercury lotion. The constant changing of the dressing—and it should be changed at least every two hours—keeps the parts perfectly clean, and thus prevents the formation of bubo. Moreover, the astringent action of a lotion such as dilute lead-water prevents the development of edema, and thus increases the local resistance of the tissues. Also there can be no doubt that although the germs do penetrate more or less deeply into the tissues, the mild antiseptics applied directly to the clean ulcerating surface also to a certain extent penetrate and inhibit growth.

The reports of clinics show, in practically all countries, that there has been an enormous diminution in the number of chancroids, and that chancrè is at the present time a much more frequent lesion. There is some reason to hope, with Peck, that in the future a greater dependence upon the medical profession on the part of the public may cause the complete disappearance of chancroid from the list of common diseases. Until that time comes, however, surgeons, and particularly those who have charge of out-patient departments, will have large numbers of chancroids to treat. It is to be hoped that if they do not succeed in abortive measures, and most important among all these perhaps is the local application of heat, they will devote their main attention to the question of local cleanliness, thorough drainage, and the avoidance of all irritating applications which may encourage local edema.

Reports on Therapeutic Progress

SUBCUTANEOUS INJECTIONS OF ARTIFICIAL SERUM IN TYPHOID FEVER.

Giglioli and Calvo (Contributo Clinico allo Studio delle Iniezioni sottocutanea di Siero Artificiale nella Fiebra Tifoidea, Florence, 1899) report the results of a series of trials of subcutaneous injections of artificial serum (physiological solution of chloride of sodium) in a recent epidemic of typhoid fever in the
outskirts of Florence. The injections were made on the outer aspect of each thigh alternately, 500 cubic centimeters of the solution being administered in one injection. Control experiments were made on two persons in good health, in whom the effect of the injections was to produce slight agitation, sweating, an abundant flow of urine, but no marked rise of temperature. Details are given of eighteen cases of varying degrees of severity and in various stages of the evolution of the disease. The phenomena of reaction following the injections consisted, generally speaking, in the majority of cases, in a characteristic modification of the thermic curve, gradual rise of temperature to the extent of 3°C., with subsequent fall to normal, slight general depression, sweating, and increased excretion of urine. The authors never observed nausea, vomiting, shivering, or mental excitement noted by other observers, and they think this probably due to the fact that in no single injection did the dose exceed 500 cubic centimeters, while the procedure was carried out slowly with slight pressure, so that absorption could take place in a slow and continuous manner. Immediately after the injection the pulse was always accelerated, but was stronger and more regular. In the majority of the cases—even in those of greatest severity, in which the temperature fell but slightly or not at all after the injection—when the reaction had ceased, an improvement in the general condition was noted, but this effect was naturally more marked in cases in which the injections caused a distinct fall of temperature and improvement in the pulse.

Summing up their results, the authors say that, while the method is not to be regarded as a specific in typhoid fever, it affords a valuable means of relieving symptoms. In cases in which the disease was relatively mild, and the temperature not too elevated, injections were followed by a marked feeling of relief and a lowering of temperature, which, however, did not become lasting till after several injections had been given. But even in the most favorable cases the authors do not feel justified in stating that the injections were the principal factor in the cure. At most they hastened it, and made it easier. In cases where the temperature was very high and the disease very severe, or in which there were cardiac or nervous complications, the effect was practically nil. The authors think, however, that in every case these injections, which are perfectly harmless, might supply a useful means of prognosis, since the intensity of reaction varies directly with the intensity of the infection, and may thus be taken as an index of the severity of the disease. —British Medical Journal, March 11, 1899.

SOME CLINICAL ASPECTS OF GRANULAR KIDNEY.

In the Lettsomian Lectures for this year WsT goes over the subject of granular kidney exhaustively, and from the British Medical Journal of March 11, 1899, we find that he has something to say of its treatment.

If we knew the causes of the disease we might take steps to prevent it; but not only are the causes unknown, but the disease is not even recognized in most cases until it is already far advanced. Little or nothing definite, therefore, can be done at present in the way of prophylaxis or prevention. But as it is in the early stages that we are likely to be able to do most good, the importance of an early diagnosis is obvious. Nor when the disease is far advanced can it be cured, for scar tissue cannot be removed from the kidney by therapeutic means any more than from the skin or from the liver.

But because we do not know at present how to prevent the disease developing, and cannot restore the diseased organs to their normal condition, it does not follow that treatment is of no avail. If we cannot treat the disease we can at any rate treat the patient; if we cannot cure the lesion we can at any rate attack the symptoms. If we can relieve the patient of the symptoms which trouble him, he will care but little for the morbid lesion; if we can cure his disease—that is, discomfort—he will not much mind the disease.

We cannot cure myxedema, but we now know how to relieve its symptoms. We may hope for similar success hereafter in the treatment of granular kidney.

The objects we should have in view in treatment are:

1. To prevent the disease getting worse, if possible, and to relieve the damaged organ in every way possible. With this in view exposure must be avoided, as well as fatigue of either mind or body; the general health should be kept at its highest level; the diet should be appropriate; and, where feasible, the winter should be spent in a warm, dry, and genial climate.

2. To guard against the accidents specially likely to occur. These are failure of the
heart and rupture of vessels. With this object violent exertion must be avoided, as well as all excessive mental work and anxiety; the patient should lead an easy life, both physical and mental; and where unavoidable illness arises, such as a severe accident or acute pneumonia, if the weak spots are remembered much may be done to diminish the risks.

3. To counteract or relieve symptoms as they arise. Dr. West, has already drawn attention to the extreme variability of these symptoms, and the treatment must therefore be correspondingly various also; but it is often surprising when the cause upon which these symptoms depend has been recognized—that is to say, when granular kidney has been diagnosed—how much may be done to give relief.

Of drugs, there is none more useful than nitrate of pilocarpine given in small doses two or three times a day by the mouth, or in urgent cases sub cutem. Thus the headache, irritability by day and restlessness by night, vomiting and digestive disturbance, a foul tongue and a dry skin, may all rapidly yield to a dose or two of pilocarpine, and the patient be restored to comfort, or even threatening symptoms of uremia be removed. There is one noteworthy fact about pilocarpine in chronic renal disease, namely, that it often does not produce the sweating which under normal circumstances and in similar doses it causes, and yet without the sweating its effect is striking.

There is one line of treatment to which Dr. West says he wishes more particularly to refer, for it has not so far been investigated as fully as it deserves, and that is the treatment of chronic renal disease by means of renal extracts. He has already said that there is no positive evidence at present of the existence of an internal secretion in the kidney; yet the cachexia which develops in chronic renal disease is not at all unlike that which is met with in Addison's disease or even myxedema. Granular kidney also presents other resemblances with these diseases, in that the grave symptoms do not arise until the organ is very considerably diseased; in fact, as Bradford has shown, it is not until about three-fourths of the total kidney substance has been destroyed that life becomes impossible.

There was the same absence of conclusive evidence in the case of the thyroid gland until the administration of thyroid extract proved by its clinical effects that the symptoms depended upon the wasting of the gland. There can be no doubt clinically that the late symptoms of granular kidney do depend upon the disappearance of the glands, and it is therefore not at all improbable that the kidney has an internal secretion, though absolute proof is not yet forthcoming.

Renal extracts have not been used except in quite the latest stages of granular kidney at a time when probably the disease is too far advanced to be amenable to treatment at all. The subject is, of course, surrounded with difficulties; and yet if we are to do any good at all by this or any other method, we must attack the disease before it has reached its later stages, and before the nutrition and general cachexia are so pronounced.

The first question is whether the administration of renal extracts by the mouth has any effect at all. As has already been said, if pilocarpine be given by the mouth or sub cutem to patients with granular kidney, the dose which under ordinary circumstances would produce free sweating often fails to produce this effect. The following experience is one which Dr. West has had on several occasions:

A patient with granular kidney who had been taking nitrate of pilocarpine regularly was given renal tablets two or three times a day. The dose of pilocarpine had hitherto caused no sweating; but within twenty-four hours or so after taking the renal tablets sweating became marked, and followed each dose to such an extent that on some occasions it had to be stopped. As soon as this was done the sweating ceased. After a short interval the pilocarpine was repeated and the sweating returned. The pilocarpine was then continued and the renal tablets stopped, and the sweating again ceased. The administration of renal tablets, therefore, did in these cases modify nutrition in some way so as to permit the nitrate of pilocarpine to have its normal action.

The most striking instance of the effect of the renal tablets occurred in the following case:

A girl, aged thirteen, was under treatment for what appeared to be acute nephritis. After some weeks' illness she began to develop uremic symptoms; the amount of albumin increased considerably; the amount of urea fell to 0.8 per cent; there was a good deal of vomiting and abdominal pain, some diarrhea, and also some bronchitis. A little later headache set in, vomiting became more troublesome, and she began to have fits. Under
treatment the fits subsided, and in the course of a week or so she was in much the same condition as before the fits commenced. As she seemed to be going down hill, renal tablets were administered in the dose of five grains twice a day. Coincidently with this she began to improve; the quantity of urine a few days after the first administration increased and reached forty-seven ounces, the largest amount she had ever passed while under treatment, the usual average being not more than fifteen or twenty ounces. With the increase in the urine the amount of albumin greatly diminished and the edema began to disappear. In the course of a month the urine averaged 1012 specific gravity, forty ounces in amount, and not more than 0.5 per cent of albumin, and soon she was well enough to leave the hospital. Some months later she returned again in a condition of dropsy and chronic uremia. She again took renal tablets with great benefit, and left the hospital well, except for the albuminuria. A third time she was brought to the hospital with uremic convulsions, and died in a few hours.

Dr. West has had two or three other cases of the same kind, and in all the results have been the same, namely, an increase in the amount of urine and an improvement in the general condition. This improvement followed and appeared to be due to the action of the remedy.

The use of renal extracts is still in a purely experimental stage. Judging by the analogy of myxedema, it would be in the cases of chronic renal cachexia only that we should look for striking results, and this requires early and correct diagnosis. In acute uremia there is so little time to act that recourse must be had to other and more active measures.

TREATMENT OF HYPERPYREXIA IN RHEUMATISM.

The Scottish Medical Journal for February, 1899, contains an interesting article on this topic by Dr. Langwill. The main conclusions he draws from the consideration of the whole subject of hyperpyrexia in rheumatism are these:

1. That the condition is more prone to occur in the warmer months of the year, and apparently with greater frequency in certain years.

2. That while it is very difficult to estimate at all accurately the frequency of its occurrence, probably this is about .5 per cent amongst adult cases of rheumatism.

3. That the occurrence of hyperpyrexia in rheumatism is practically confined to cases of this disease in persons over fourteen years of age.

4. That the rare instances of hyperpyrexia which occur under that age are in cases of rheumatism which present the adult type of the disease.

5. That the absence of hyperpyrexia from rheumatism in children is probably to be explained as the result of the type rheumatism assumes in them rather than a mere question of the age of the sufferer.

6. That males show a much greater proclivity to the condition than females, which may possibly be associated with the greater strain habitually put upon their thermotaxis mechanism.

7. That the condition is most apt to occur in "first attacks" of rheumatism.

8. That persons who have once suffered from the condition would probably be apt to have a recurrence of it in any subsequent attack of the disease (although no case of such recurrence has previously been published).

9. That it may ensue at any stage in an attack of rheumatism, but probably the second week is the most common period of its occurrence.

10. That it may arise in even mild cases of rheumatism, severe rheumatic symptoms being no essential to its occurrence.

11. That the onset of hyperpyrexia, while occasionally without warning, has usually premonitory symptoms, the chief of which is delirium.

12. That cases of true rheumatism showing persistence of the pyrexia, in spite of full doses of the salicyl compounds, should be most carefully watched, since hyperpyrexia frequently ensues in such instances.

13. That sudden cessation of the articular pains without coincident fall of temperature should lead to the suspicion of hyperpyrexia, especially if attended also by the cessation of sweating.

14. That Maclagan's hypothesis that hyperpyrexia is due to paresis of the heat-inhibiting mechanism from exhaustion in its attempt to control the excessive heat-production of rheumatism is the most feasible theory yet put forward in explanation of the condition, satisfactorily accounting for the more frequent occurrence of hyperpyrexia in adults than in children.

15. That the absence of rheumatic hyperpyrexia in children is a strong argument
against the view that this condition is due to visceral complications, since it is especially in children that these visceral manifestations occur, and it is just in those cases that hyperpyrexia is not found.

16. That in view of the resemblance in several respects between rheumatic hyperpyrexia and "diabetic coma," further investigation of this subject might possibly throw fresh light upon the pathogenesis of both conditions.

17. That while the mortality of rheumatism is only about three per cent, hyperpyrexia is probably one of the most important immediate causes of death in this disease.

18. That the mortality of hyperpyretic cases is very high—probably over fifty per cent—but statistics are very variable because

19. The mortality is greater the higher the temperature before treatment is begun; and

20. It is also greater amongst cases treated by means of antipyretic drugs alone.

21. That treatment by the application of cold in one of its various forms is the only justifiable method in cases of hyperpyrexia in rheumatism.

22. That this should be adopted even in cases apparently moribund, and even although visceral complications may be present.

23. That while there may possibly be some risk of congestion of internal organs as a result of this method of treatment, this does not justify the neglect of what is practically the only remedy for an otherwise fatal condition.

24. That the greatest care should be taken to prevent collapse ensuing in the patient as a result of the treatment by cold, which should be stopped entirely before the temperature falls to normal.

25. That antipyretic drugs, while practically useless in the treatment of hyperpyrexia when present, may perhaps be of some service in preventing a recurrence of this after the temperature has once been reduced by means of cold.

26. That in obstinate cases of recurrent hyperpyrexia the method of treatment by "disintoxication of the blood" adopted by Barré may probably be of service as an adjuvant to the treatment by means of cold.

27. That greater attention should be paid to the prophylaxis of rheumatic hyperpyrexia, and that more prominence should be given to the advantage of commencing treatment by cold at an early stage before excessive temperatures are attained; in other words, the general condition of the patient, rather than the mere height of his temperature, should be the determining factor for commencing the treatment by cold.

28. That early and complete subjection of the patient to antirheumatic treatment would probably have some influence in preventing the occurrence of hyperpyrexia.

NOTES ON COCAINE.

Jenney, of Deadwood, contributes some of his views in regard to cocaine to the Medical Record of March 25, 1899, and considers its influence upon the skin at the beginning of his paper. He believes that when an aqueous solution of cocaine is applied to the skin, a portion of the drug is absorbed and a peculiar sensation of coolness pervades the part, and if the action is long continued over a considerable surface the amount absorbed may become so great as to cause in some cases physiological symptoms resembling those described as produced by chewing the leaves of the coca plant. Although the quantity of cocaine so applied to the skin may be many times the maximum dose which may be given internally or hypodermically with safety, no toxic action takes place. The local anesthetic effects peculiar to cocaine are somewhat modified; sensation continues in the surface treated with the solution even after the lapse of twenty to thirty minutes. In the treatment of bruises resulting from a blow or similar cause, the action is most strongly marked; the discoloration and congestion of the tissues are rapidly reduced to the normal color of the skin, evidently by the constriction of the blood-vessels; inflammation and pain subside more gradually, and the pain seldom returns after the anesthetic effect of the drug has ceased. If the locus of the pain is near the surface, relief is usually speedy, not infrequently all pain subsiding permanently in three or four minutes; where more deep seated, the action is retarded and less often permanent in its effects. It is then necessary to keep the surface of the body directly over the seat of the pain wet with successive applications of the solution, until ten or more grains of cocaine hydrochlorate has been used. In such cases relief from pain comes very gradually, and may probably be due to the physiological action of the alkaloid through the circulation, rather than to cocaine anesthesia by direct absorption. This view is confirmed by a few instances in which the amount of the drug applied to the skin was from fifteen to twenty
grains, the patient displaying a high state of nervous excitement much resembling the effect produced by an excessive amount of green tea. Respiration was increased and the pupils dilated, without the manifestation of any of the distinctly toxic symptoms of cocaine. It is noteworthy that these physiological symptoms, with the absence of toxic action, are those recorded as resulting from chewing the leaves of the Erythroxylon Coca.

The strength of the solution, while somewhat influencing the rate of absorption of the alkaloid by the skin, does not appear to be an important factor. A solution of two to four per cent, or from ten to twenty grains of cocaine hydrochlorate per ounce of water, has been found to give good results. It is best that the solution should be freshly prepared, as it undergoes decomposition in a few days.

The solution may be applied by painting the surface of the skin with a camel's-hair brush, or a cloth, or a thin sheet of absorbent cotton wet with the solution may be placed in direct contact with the skin over the part affected. All absorption ceases if the surface becomes dry, so that it is necessary to paint the spot repeatedly with fresh solution or to wet the cloth with water to replace loss by evaporation due to the heat of the body.

The action varies in some degree with samples of cocaine hydrochlorate of different manufacture; the crystallized drug, put up in sealed bottles, is more rapidly absorbed by the skin than the preparations (which Dr. Jenney has tested) that are sold in bulk.

The therapeutic action of cocaine upon the human skin appears to have escaped the attention of investigators. Most of the standard works on the subject either omit any mention or state that the drug is not absorbed.

Cocaine solution may be employed as above indicated in the treatment of bruises, sprains, and many local inflammations of like character. As a "pain paint" in the quick reduction of bruises, it is doubtful if it has any equal. It may also be used as a preliminary application to reduce inflammation in surgical treatment of dislocations and fractures.

In neuralgia, when the nerve affected is situated near the skin, the local application of a sheet of absorbent cotton saturated with cocaine solution will in some cases give almost immediate relief. It is also worthy of trial in pleurisy, pneumonia, and peritonitis; a gradual palliative action has been observed to take place by prolonged application of a six-per-cent solution, notwithstanding the deep-seated locus of the inflammation; the action, in part at least, being probably due to the absorption of the alkaloid into the circulation. In like manner the dull, persistent pain in the lungs in tuberculosis is in some instances alleviated by the repeated application of cocaine to the chest. Small and painful wounds where the skin is practically unbroken may be treated directly with cocaine without danger of too rapid absorption of the drug. In a wound in the foot caused by stepping on a rusty nail, wetting the bandage with cocaine solution reduced the inflammation and quieted the pain, the wound healing with comparatively little suffering to the patient.

Painting with cocaine the marks due to the hypodermic syringe causes them to disappear quickly, from the constricting of the blood-vessels.

Caution should be exercised in the external application of cocaine in cases in which the surface of the skin is not intact, to open wounds, or highly inflamed surfaces, lest absorption of the toxic alkaloids should occur.

The rapid absorption into the circulation of the toxic alkaloids when cocaine is administered internally affords an explanation of the danger incident to the employment of more than the smallest doses administered through the mouth, rectum, or urethra; to the introduction beneath the skin by the hypodermic needle; or to the application of a solution of the drug to any mucous surface.

There are some evidences in the action of a solution of cocaine hydrochlorate when applied to the human skin which indicate that the drug as supplied to the trade may not consist of a simple substance, but of a mixture of at least two alkaloids—one, rapidly absorbed by the skin, is non-poisonous and possesses valuable properties in the reduction of local inflammation and pain; the other, to which is probably due the toxic action, is not absorbed and is left as a residuum on the surface of the skin. In short, it seems that when wet with a dilute solution of cocaine hydrochlorate, the human skin apparently dialyzes the mixed alkaloids, permitting the harmless alkaloid to be absorbed, separating it from the toxic principles. In an experiment a thin sheet of absorbent cotton three inches square was saturated with a six-per-cent solution of cocaine and applied to the skin of the patient for half an hour,
the cotton being kept moistened with water to replace the loss by evaporation. When there was no longer any sensation noticeable from the absorption of the drug, the cotton was washed with water and the washings were evaporated in a watch-glass by steam heat. The residuum was a white, solid substance, having an intensely bitter taste and producing an almost instantaneous sensation of numbness when a small particle was applied to the tongue.

The variable action of cocaine noted by investigators, and the erratic poisonous action, in certain recorded cases of even the smallest doses when administered internally, may be explained by the irregular composition of different samples of the drug; some containing a larger portion of the highly toxic alkaloids, while other preparations have a greater percentage of the non-poisonous alkaloids.

Should the suggestions here put forth respecting the composition of cocaine be confirmed by chemical research, it is not improbable that other animal membranes will be found on experiment to act like the human skin in separating by dialysis the valuable alkaloid from the toxic principle.

There is thus hope that cocaine may be in the future prepared free from all poisonous principles; should this hope be realized, Dr. Jenney suggests that cocaine be retained as the name of the valuable alkaloid, and that lethane be the designation of the toxic element.

THE QUESTION OF INFLATING THE BLADDER WITH AIR PRELIMINARY TO THE BOTTINI OPERATION.

A discussion has been going on among surgeons as to the question which heads this item, and as the matter is of great importance to those who perform this operation we take pleasure in quoting from an article by Lewis, of St. Louis, in the Medical Record of March 25, 1899.

In a discussion of the Bottini operation for senile hypertrophied prostate, held at a meeting of the New York Deutsche Medicinische Gesellschaft, May 2, 1898, Dr. Freudenberg called attention to a feature of the operation that might prove dangerous in certain cases—indeed, that had proved disastrous in one of his own; that is, when the bladder is empty, with its mucous membrane lying in folds, there is liability of the heated platinum blade catching in one of the folds and burning through it, or even through the bladder wall, with peritonitis and death as a result. To obviate this, Dr. Freudenberg recommended that the bladder be at least partially filled with boric acid solution in order to smooth out the membrane and its folds.

In carrying out this suggestion in a subsequent operation on a patient on whom Dr. Lewis had already operated with the bladder empty, he found that the pain was enormously increased—was, indeed, unbearable—whereas in the previous operation on the same patient it had been of small moment. He therefore substituted air as a distending medium, with the effect of reducing the pain to practically nothing. Cocaine anesthesia was used in each instance.

It appeared probable to Dr. Lewis that the superheated boric solution in the neighborhood of the red-hot blade had caused a scalding effect, with the production of the exaggerated pain. From the result of an experiment he was made doubtful of the expediency of this method, even aside from the question of the amount of pain which it might induce. On placing the blade in a cup of water and turning on the electric current, the water would be made to boil, but the blade could not be brought to a red heat, no matter how strong a current was used.

Dr. Freudenberg believes that by causing the incisor to hug the prostate closely, the solution may be excluded from coming in contact with the blade. This Dr. Lewis thinks very doubtful, as the probability is that when the blade is drawn from its niche an opening is made for the ingress of the solution, interfering with the working of the instrument, as well as producing an unnecessary scalding effect.

Dr. Lewis' use of air inflation in connection with this operation was mentioned in the Medical Record of November 12, 1898, page 718, and the Philadelphia Medical Journal of December 10, 1898. In an able and gratifying report of his cases Dr. W. Meyer, of New York, writes as follows on the subject of inflation: "Lewis, of St. Louis, recently recommended the advisability of filling the bladder with air. One of his patients, on whom he had to operate a second time, maintained that there was no pain whatever after air had been injected into the bladder, while when it had been filled with water previous to the first operation the pain was considerable. I should not, however, indorse vesical inflation with air. The experiments of Lewin and Goldschmidt have shown that, owing to some unforeseen gaping of the ureteral openings, the
air may ascend from the bladder into the pelvis of the kidney and then pass, by way of the renal vein, into the general circulation. Death from an aerial embolism into the pulmonary artery may set in."

On looking up the reports of the experiments of Lewin and Goldschmidt, Dr. Lewis says he found them to be in effect as follows (the conclusions of the authors): "Air, being injected into the bladder (of a dog), in case it ascends into the ureter produces the following effects: The kidney enlarges and turns somewhat on its axis. With a fine, peculiar noise air-bubbles pass from the direction of the kidney hilus into the renal vein. There is noticed a slight vibration; in a short time the blood is forced out and the vessel resembles a round empty tube of frosted ('milch') glass. The bubbles pass into the vena cava, fill it, replacing the blood, and, after a few spasmodic motions of the extremities, the animal dies. On opening the chest, one can see how the heart still works for a time with spasmodic efforts; through its thin anterior walls one can further observe how by the activity of that muscle the blood is churned into foam, intermingled with air as it is. We have clearly established, therefore, a transportation of air from the urinary channels into the blood-vascular system."

Dr. Lewis says, on reading so graphic a description of this remarkable and acrobatic performance, he was staggered. So imminent a peril as this to beset the lives of patients being operated almost daily by Dr. Howard Kelly and his disciples, in the cystoscopy of women; so many undergoing its dangers at the hands of the followers of Dr. Bristow, who advocated the employment of air for vesical distention in ordinary episiotomy, and whose advice has been accepted in the practice of many prominent surgeons of this country, is difficult to contemplate. He was reassured to some degree, however, by remembering the results of experiments conducted by Dr. H. A. Hare in 1889, in which the old idea of the extreme harmfulness of air in the circulation had apparently been exploded. In these experiments upward of seventy dogs had been subjected to air injections.

From this series of experiments the author deduced the conclusion that "death never occurs from the entrance of air into the ordinary veins of the body unless the quantity be enormous—from one to several pints, a quantity which cannot enter unless deliberately sent in by the surgeon."

However, being desirous of arriving at an unbiased and correct conclusion regarding the vesical inflation question, Dr. Lewis carried out the following experimental steps on a dog. They were done with the assistance of Dr. H. I. Niertert, superintendent of the City Hospital, Dr. R. Amyx, assistant superintendent, and Dr. Greiner, all of whom watched critically the various stages of the procedure, and agreed that no opportunity was overlooked for getting a confirmation of the results of Lewin and Goldschmidt; but, as will be seen, not a particle of evidence in confirmation of them was obtained.

The dog was a half-grown mongrel, weighing about nine pounds. Under chloroform anesthesia the abdomen was opened from symphysis to enisiform cartilage, and the intestines were drawn aside, giving a perfect view of the field of observation. With a rubber bulb syringe the bladder was completely distended with air, after withdrawal of its urinary contents. The penis was ligated, preventing the escape in that direction of the injected air. With the left ureter, kidney, and renal vein plainly exposed to view, firm compression was made on the distended bladder, and continued for fifteen minutes. No distention of kidney pelvis or of ureter ensued. The position of the bladder was changed in various directions, to afford the best opportunity possible for the escape of the air into the ureters, but with the same negative result. Each of the onlookers tried various manipulations of the bladder, but without succeeding in getting the air up into the ureters (both ureters were watched in the maneuvers); and finally sufficient compression was used to rupture the bladder wall, without overcoming the integrity of the vesicoureteral valves.

Next a hypodermic needle was introduced through a ureteral wall, and a syringeful of air was sent toward the kidney pelvis. This latter was distended to a certain degree, which condition was maintained for five minutes or more by compression of the ureter below it. The renal vein was closely observed. Not a bubble appeared in it, nor did it undergo a single change suggestive of inflowing air. The kidney position was changed in several ways, to facilitate the "filtration" of the air through it, but still without result.

In order to make this feature of the experiment satisfying to even the most skeptical, a slit was made in the wall of the ureter, a cannula was introduced through it, and the bulb
syringe (Politzer air-bag), attached to the outer extremity of this latter, enabled them to make forced air-pressure into ureter and hilus, sufficient almost to burst them. This pressure was likewise maintained for ten or more minutes; yet no bubble appeared in the renal veins and no "milk-glass" appearance was assumed by it—in fact, there was no transportation of air from urinary channels to renal or other vascular system. And meanwhile the dog slept serenely.

Next, in order to see what effect would follow if the air should be transferred into the venous system, Dr. Lewis injected three hypodermic syringefuls in rapid succession into a mesenteric vein. The air could be plainly seen to shoot along toward the center, indicated by the displaced blood. The dog showed no disturbance in breathing as a consequence, but slept placidly and continuously for a half-hour thereafter, and was awakened when we killed him with a double dose of chloroform.

From the above there seems little probability that any noxious effect would ensue, in a Bottini operation with air inflation, even if there should be "some unforeseen gaping of the ureteral openings." The kidney makes an impermeable barrier against the entrance of air into the circulation from that source; and even if it did not, the injurious effects of such transportation are problematic, to say the least. As Dr. Hare says, whereas there have been numerous cases reported in which sudden death occurred during operations in which veins were opened, in the majority of them the cause of death has been guessed at and not proved as being due to the entrance of air. He asserts that not a single instance has been proved to be due to that cause.

In a recent private communication to Dr. Lewis on the subject under discussion, Dr. Hare writes: "Even if by reason of disease the ureteral valvular protection were removed, it seems incredible that, should the air pass up the pelvis to the kidney, it could enter the renal vein and so get into the general circulation."

But to pass from speculation and experiment to the evidence furnished by the clinic. Dr. Lewis says he wishes to present the testimony of operators in this field. With a view to obtaining this, the following note was recently addressed to several surgeons: "Will you kindly inform me: (1) If you have made use of air inflation of the bladder in connection with epicystotomy or other operative procedure. (2) If you have ever met with any injurious or disastrous effect therefrom. (3) If you have ever heard of any such in the practice of other surgeons (names unnecessary)."

Responses were had from Drs. W. W. Keen, Philadelphia; J. B. Murphy, Chicago; Howard A. Kelly, Baltimore; John H. Brinton, Philadelphia; William T. Belfield, Chicago; J. William White, Philadelphia; John P. Bryson, St. Louis; and Maurice H. Richardson, Boston.

There is such a unanimity of sentiment in these expressions that it is not necessary to quote them separately. In response to the first question there are affirmative answers from five of the gentlemen: "Yes, many times," from Drs. Kelly, Belfield, and Bryson, and simply "Yes" from Drs. Keen and Brinton. The other three gentlemen have not used air inflation. In response to the second and third questions "No" is the unanimous answer. Dr. Lewis says that in the several instances in which he has used air inflation he has seen no indication of trouble of any kind from it, nor has he ever heard of any in the practice of any surgeon.

It seems altogether probable that if vesical inflation had ever given rise to the disastrous consequences feared, it would have come to the knowledge of some of the operators mentioned above, even if it had not occurred in their practice.

From the evidence adduced it would seem unjust, Dr. Lewis believes, to rest an objection to vesical inflation on the ground of possible danger.

THE ETIOLOGY AND TREATMENT OF NEURASTHENIA; AN ANALYSIS OF THREE HUNDRED AND THIRTY-THREE CASES.

Collins and Phillips in the Medical Record of March 25, 1899, after writing extensively upon this subject, tell us that in their opinion the medicinal treatment of neurasthenia is the least important duty of the physician, though it is oftentimes difficult to convince the patient of this, and physicians as well. Symptom medicines are invaluable to meet certain indications, and disease medicines assist in overcoming certain organic conditions, such as anemia; but despite this the majority of neurasthenic patients would reach the goal of recovery just as surely and speedily if drugs were entirely discarded. At least it may truthfully be said that it is oftentimes as important to forbid the patients all medica-
tion as it is to prescribe it. Neurologists will probably agree that the majority of patients who come to them for advice and treatment, after they have been under treatment by their family physician or desultorily by a number of physicians, are so thoroughly bromized that this state demands treatment. Dr. Collins does not mean to say that the bromide salts are not oftentimes of signal benefit to relieve certain distressing symptoms, such as head pressure, cardiac palpitation, abdominal fluttering, etc.; but they should never be given continuously, promiscuously, or without special indication. Although the Pharmacopoeia contains no drug that has special virtue to “strengthen” the nervous system or to restore its equilibrium when the balance is once disturbed, there are certain drugs which, by creating an appetite, facilitating digestion and assimilation, forcing oxidation and elimination, and by adding to the constituents of the blood, are serviceable when such indications exist. The simple bitters and stomachics can be given for a short time with a considerable confidence that they will cause a greater relish for food. Arsenic, nux vomica, and quinine oftentimes not only create a greater desire for food but seem to have a general tonic effect, particularly upon the muscular system. Cod-liver oil, which is supposed to be of especial service in the treatment of neurasthenia, has no other virtue than to provide an easily digested carbonaceous food.

In anemic individuals suitable preparations of iron and arsenic, alternated or combined with the simple bitters, must be given. In administering iron it should never be forgotten that it has been proven experimentally that the quantity which the blood will take up stands in no relationship to the amount administered. Not infrequently beneficial effects follow repeated inhalation of oxygen. This procedure not only affords a general fillip to the system, but has a desirable mental effect. In the use of arsenic and quinine it is well to bear in mind that the former has a tendency to produce disturbance of the stomach and intestines which may have a very distressing mental effect upon the patient; while the latter, if given in other than very small doses, is sure to produce ringing in the ears and vertigo, which the patient will be likely to interpret as most disastrous manifestations.

The administration of aphrodisiacs in sexual neurasthenia is conceived in error, and should never be tried except for the mental effects. Drugs that make powerful appeal to the mind by insinuting one of the special senses—such as valerian, for example, particularly when given with assurance that it will be beneficial—are oftentimes of great comfort to the patient, and thereby useful. Hypnotics are rarely necessary when rest and exercise, hydrotherapy, and massage are properly and faithfully utilized. It is oftentimes necessary to give one of the simpler hypnotics a few times, in order to secure sleep until the physical measures just mentioned have time to become effective. They should be given in sufficiently large doses to make their effect decided, so that the patient may be impressed that a medium is readily at hand that can easily cope with the insomnia.

Reference has already been made to the absurdity of depending upon local treatment alone to cure neurasthenia, whether such treatment be directed to the prostate, the eye muscles, the uterus, or the stomach. All these organs are very liable to reveal considerable disorder of function in neurasthenia, but so does every other tissue or organ of the body in varying degree. They all need treatment, and thus it is that hydriatic procedure, diet, rest, exercise, etc., have proven to be the really trustworthy therapeutic agencies. Occasionally neurasthenia occurs as a result of rectal abscess and fistula, of enlarged prostate, of prolonged and the excessive use of ill-balanced eye muscles. In every such case the effort should be made to rid the patient of these evident infirmities; this is tantamount to saying that the causal treatment of neurasthenia should never be neglected. If such treatment suffices, the patient and the physician have good cause for mutual congratulation. Unfortunately, however, it does not suffice in about ninety per cent of the cases, and it is unwise to neglect the ninety merely to reach the ten.

THE PATHOLOGY OF THE THYROID GLAND.

Murray, of England, to whom we owe so much in the study of thyroid therapy, is delivering the Goulstonian Lectures for 1899 and considering the thyroid gland. In The Lancet of March 11, 1899, he tells us that in advanced cases of myxedema the first stage of the treatment must be carried out with great caution, especially if any symptoms of degeneration of the cardiac muscle, such as attacks of syncope, dyspnea on exer-
tion, feeble or irregular pulse, or weak heart sounds, are present. Under these circumstances the patient should be confined to bed at first and only small doses of from one-quarter to half a grain of thyroid given each night. This dose if well borne may be gradually increased up to ten minims. If not confined to bed these patients are apt to make use of their returning vigor too soon, before the heart has had time to recover and adapt itself to the altered conditions brought about by the treatment. These advanced cases in which little exercise has been taken for months or even years are now rare, but in the early days of the treatment the importance of this caution was painfully impressed upon Dr. Murray by the deaths of two patients from syncope who had cardiac disease, after they had practically got rid of the symptoms of myxedema. Any undue acceleration of the pulse up to 90 or 100 indicates that a reduction should be made in the dose, and any signs of cardiac failure must be met by giving stimulants and digitalis.

By far the greater number of cases which require treatment are now seen in the early stages of the disease before any cardiac symptoms have developed. In these, the patient is able to go about as usual, though it is advisable to avoid any unusual exertion during the first stage of the treatment. A daily dose of ten minims of thyroid extract may be given each night from the beginning and increased to fifteen minims at the end of a fortnight, if decided improvement has not already taken place. Any marked increase in the frequency of the pulse or rapid loss of weight is an indication for at once reducing the dose. Symptoms of gastrointestinal catarrh have sometimes arisen during this first stage of the treatment, especially if the raw gland has been used. They rarely if ever appear if a suitable preparation of the gland is used instead. If they do occur, the thyroid treatment should be stopped until they have passed away, and then smaller doses should be given, when the treatment is again commenced. In many cases no other treatment beyond the daily dose of thyroid extract is required. When, however, there is a well marked anemia it is a good plan to give iron as well as thyroid extract. Five grains of dried sulphate of iron in a pill twice or thrice daily after meals is a suitable form in which to give it.

As soon as all the symptoms of myxedema have disappeared the first stage of the treatment is completed. The second stage then commences and must of necessity last as long as the patient lives. During this stage the patient must continue steadily to take a daily dose of thyroid extract equivalent to the daily output of the gland before it became diseased, or at any rate of that part of it which has become functionless. It is important that patients should understand this and that good health can only be maintained by the continued use of the remedy. To insure this it is often better to describe the remedy as an essential part of the daily diet and not as a medicine, so as to overcome the objection some persons have to taking what they regard as a medicine for such long periods. Of course an occasional intermission of the treatment for a week or so has little or no effect, but if no thyroid extract is taken for three or four weeks the temperature falls one or two degrees below normal, and the myxedematous swelling of the face begins to develop again. If the extract is omitted for a longer period still all the original symptoms gradually reappear, till at the end of three or four months the condition will be much the same as it was before any treatment was adopted. The most suitable dose for the second stage of the treatment is, generally speaking, ten minims of the extract given once a day. If after a time any slight symptoms of myxedema reappear, the permanent dose should be increased to twelve or fifteen minims. In none of Dr. Murray's cases has it been necessary to give more than ten minims; in a few cases this dose is too large, as after a time it produces acceleration of the pulse. The permanent dose has then to be fixed at five or seven minims a day.

In doubtful cases of myxedema thyroid extract may be given as a means of diagnosis. For this purpose a dose of ten minims should be given daily for three or four weeks. If the symptoms steadily diminish they are the result of thyroidal disease; if, on the other hand, no improvement takes place they are due to some other cause. This test is of great use in distinguishing some of the cases with anemia and subcutaneous swelling from cases of anemia with ordinary obesity, which they often closely resemble.

When the treatment of a well marked case of myxedema is carried out on the lines just indicated, very definite and interesting results are soon obtained. One of the earliest signs of improvement is in the return of the temperature to the normal level. This is illus-
TREATMENT OFcretinism.

We have already quoted from Murray's lecture in The Lancet of March 11, 1899, upon the thyroid gland. The results of athyroidism in young animals and children are more serious than in the adult owing to the arrest of development. The treatment of a cretin consequently presents a more formidable task, but the results are in some respects even more interesting than those just described in myxedema. Murray again points out the importance of carefully considering the possibility of the presence of disease or lack of development of the thyroid gland in every case of arrest or delay of development in children. In all such cases it is important to look for slight signs of cretinism. There are of course other causes of arrest of growth, such as achondroplasia, but Dr. Murray has seen several cases where the ordinary symptoms of cretinism were not distinct and might easily escape observation if not searched for carefully, in which the rapid improvement following thyroid treatment has proved that the arrest of development was due to thyroidal insufficiency. The importance of early diagnosis in such cases lies in the fact that the earlier the treatment is commenced the better prospect there is of normal development of the central nervous system. Experience has already shown that in cretinism of some years' duration, rapid as the improvement in the physical condition may be, the intellectual development is much slower; so that when treatment is commenced late it is doubtful if the latter will ever advance as far as when treatment is started early. If any doubt exists as to the diagnosis it is a good plan to carry out the treatment for one or two months. If no distinct improvement takes place the want of development is not due to cretinism, for in other forms of arrested growth the treatment has comparatively little effect, though it is worthy of trial.

The treatment of early cretinism is carried out on the same lines as the treatment of myxedema in the adult. During the first stage gradually increasing doses of thyroid extract are given till the symptoms disappear. It is advisable in treating a small cretin to begin with a dose of one or two minims each evening, gradually increased by the addition of one minim each week or fortnight until a dose of five, seven, or ten minims, according to the size of the child, is reached. As the child gets older it may be found necessary to increase the daily dose.
from time to time by the addition of another
minim. If too large doses are given the
pulse becomes too frequent, pains may be
felt in the limbs and elsewhere, the tempera-
ture may rise above the normal level, and
purging may follow. As in the adult, the
treatment must be continued as long as the
patient lives. As soon as the symptoms have
disappeared it is only necessary to determine
the most suitable permanent dose and to in-
sure its uninterrupted administration.

In the treatment of cretinism which has
lasted for some years we have a much more
difficult task to perform, but very good re-
sults can be obtained. Even when the dis-
ease has lasted ten or twelve years, provided
the patient is not more than eighteen or
twenty years old, a remarkable amount of
growth can still take place. In these cases
from three to five minims of thyroid extract
may be given at the commencement and in-
creased according to the progress observed.
Even in cases in which the symptoms had lasted
for twenty or twenty-five years some growth
and marked improvement in all the sym-
ptoms take place. In cases of long duration
attacks of syncope are not uncommon. In
such the earlier part of the treatment is more
safely accomplished by keeping the patient
in bed and giving small doses of one or two
minims only at first.

When the necessary stimulus to the normal
metabolism of growth is thus supplied to a
cretin in the early stages of the disease the
symptoms disappear. The swelling gradu-
ally diminishes in all parts of the body. The
tongue, lips, and nose diminish in size, so that
the appearance becomes natural. The skin
becomes soft and moist and the temperature
rises to normal. Growth, which at this early
stage will only have been partially arrested,
starts afresh. If the treatment is continu-
ously carried on in such a case from the
earliest time in which the disease is recog-
nizable there seems no reason to doubt that
ultimately the child will grow up into a fully
developed healthy adult, who, however, would
of course at any time develop symptoms of
myxedema if his supply of the extract was
discontinued. The intellectual development
is always much slower than the bodily growth
and general improvement in all other re-
spects. The shorter the duration of the
symptoms has been at the commencement of
the treatment the more rapid the improve-
ment in the mental condition, and Dr. Mur-
ray thinks it is only in cases in which the
treatment is started early that we can expect
normal intellectual development to take
place. In cases of some duration it is im-
portant that a special education should be
carried on at the same time as the treatment,
in order that the patient may be able to make
the most of the renewed cerebral activity.

THE TREATMENT OF OZENA WITH SPE-
CIAL REFERENCE TO CUPRIC
ELECTROLYSIS.

M’Bride writes in the Edinburgh Medical
Journal for March, 1899, upon this novel
theme.

According to Moure, Garrigou Désarènes
was the first author who proposed the employ-
ment of electrolysis. He, however, applied
only one pole to the surface of the nasal mu-
cosa, while the other rested upon the neck or
some other indifferent part. His method was
followed in a more or less modified manner
by Delavan, of New York. Then Joussain
suggested interstitial cupric electrolysis, in
an article which unfortunately has not been
accessible to Dr. M’Bride, but which Moure
states was communicated to a French sci-
centific society in 1892. This method of treat-
ment was not apparently referred to again
until 1895. Cheval then described it, and at
the same time recorded ninety per cent of
cures, and in seventy of his cases attained
this result after a single séance. His paper
was communicated to the Society of Belgian
Laryngologists and Otologists, and later this
body appointed a committee of four to in-
quire into the effects of cupric electrolysis.
Seven cases were treated by Cheval, and in
none of them could the members find any
improvement. In 1896 Bayer gave a long
account of the method and its results, which,
according to him, were extremely good in a
large proportion of cases. During the fol-
lowing year Réthi expressed the opinion that
the benefits obtained from cupric electrolysis
were greater than those derived from any
other method of treatment.

Brindel, at the suggestion of Moure, under-
took the treatment of thirty cases in the
clinic of the latter. He found that in every
instance the nasal affection was modified for
some days; the mucosa became swollen, red,
and congested; the yellowish-green thick
crusts no longer formed on the side operated
upon, but in their place sticky mucus, some-
times tinged with blood, was found, while
fetor disappeared. Brindel, however, ob-
served that relapses often occurred after from
one to eight weeks. Nevertheless, in ten cases
permanent benefit followed the treatment. In none of these, at the time of writing, were there either crusts or odor, the patients having been under observation from three to eleven months.

The latest work upon cupric electrolysis with which Dr. M'Brude is acquainted emanates from Gouguenheim and Lombard, who arrive at the conclusion that cupric electrolysis has a definite action on ozena, causing disappearance of fetor, but that it is not possible to say that the result will be permanent.

Dr. M'Brude says he does not think that cupric electrolysis, has yet been touched upon in English literature, and with one exception its use seems to have been, so far, confined to Belgium and France. Struck by the preponderance of favorable evidence, he began to experiment with this treatment in 1897, and gives his results briefly.

The strength of current varied from three to ten milliamperes, rarely exceeding the latter. Cocaine was used in most if not in all cases, and after cleansing the nostrils the copper needle attached to the positive pole was inserted into the inferior or middle turbinate, sometimes into the tissues lining the middle meatus, while the platinum (or steel) needle was passed into the septum. Usually the patients complained of little pain, nor did they experience disagreeable after-effects. A private patient on whom Dr. M'Brude recently performed electrolysis, however, suffered a good deal from neuralgia, swelling of the eye, and general disturbance for a day or two. As a rule, each sitting lasted about ten minutes. As he has stated before, the cases quoted were not selected by him, but it is just possible, nevertheless, that a process of natural selection may have been brought about. They all occurred in out-patients, and it is quite conceivable that the majority of those who were benefited repeatedly presented themselves, while there may have been an opposite tendency on the part of those who received little relief. It will be noted that out of the eight patients whose histories he gives briefly four were practically cured for long periods, extending to eighteen months. In one there was marked improvement; in another case apparent cure for some months, but then syringing had to be resumed; while in two cases there was only improvement for a few weeks. The former was shown to the audience, and Dr. M'Brude thinks that the fetor has been practically cured, but the patient complains of the dis-

comfort caused by crusts accumulating in the nasopharynx and larynx.

In the last sentence, when Dr. M'Brude uses the term "cure," he says he refers to the fetor, for in most of the cases the atrophy remained as before. He is quite prepared to admit, as above stated, that the results achieved in these seven cases may have been beyond what we can reasonably expect to average. Still they prove that in cupric electrolysis we have a valuable therapeutic resource, probably the most valuable that has yet been suggested, for ozena. The rationale of the treatment is still uncertain, but probably the formation of copper salts at the positive pole has at least as much effect as the electric current.

THE OUTLINE TREATMENT OF MIGRAINE.

In _La Presse Médicale_ of February 11, 1899, Gallois stated that in gouty migraine depending upon uric acid he believes that the constant use of large doses of bicarbonate of sodium is advisable, and directs the patient to take a saltspoonful of bicarbonate of sodium in each quart of water, which quantity shall be taken in each twenty-four hours. He states that three cases of inveterate migraine have been treated in this manner with excellent results.

WHAT TO DO AND WHAT NOT TO DO IN THE TREATMENT OF CERTAIN OF THE MOST FREQUENT EAR AFFECTIONS.

We have already abstracted part of an article with this title, by Haug, which is published in the _Eye, Ear, and Throat Journal_ for January, 1899. He further tells us that atresia of the meatus may occur in injuries or ulceration of its walls and especially after burns. In such cases strips of gauze must be introduced into the meatus past the seat of the lesion, after previous moist or dry cleaning of the meatus. These are much more effective than perforated drainage-tubes and supplant mechanical dilators, tents, etc.

Eczema may cause agglutination and eventually atresia. This is best prevented, and the eczema at the same time treated, by strips of gauze impregnated with ointment (diachylon ointment, oleo cocti, zinc ointment, equal parts). Even when nearly well the tamponade must be continued either dry or after painting with
Naphthol B, 0.1;
Acid salicylic, 0.5;
Alcohol, 35.0;
Glycerin, 15.0.

until the skin is smooth and scales have disappeared.

The air-douche and its proper performance will now receive our consideration.

First, it cannot be too urgently insisted upon that all the instruments that are used (catheters, nasal olives, etc.) should be sterilized, to avoid syphilitic or other infection. As to the air-douche itself, there is no doubt that in it, whether carried out by the simple Valsalva procedure, by Politzer’s method, or by the catheter, we have one of the best means of improving and curing a large portion of the defects of the hearing apparatus which depend upon a disturbance of the middle ear. On account of their easy accomplishment, Valsalva’s and Politzer’s procedures have become the property of the laity. Catheterization requires a certain skillfulness which is usually confined to the physician. While it is probably in itself a matter of congratulation that a good method of treatment should find universal extension, still the abuse of this method may provoke the danger either of making the disease worse or of producing such a one; while capable of the greatest good, still, if used at the wrong time and place, the air-douche can cause endless injury.

Not long since it was the fashion on the part of the practitioner and even the specialist to “air-douche” every variety of ear disease, and the patient soon learned to treat himself by Valsalva’s and Politzer’s methods.

In this connection two questions arise:

1. Can the air-douche under certain circumstances work injury?

2. When can and ought we to apply the air-douche for the relief of existent affections of the hearing?

The first question must be answered with a “yes.” In accord with physical laws and following the path of least resistance, whenever air is compressed in the nasopharynx it extends through the Eustachian tubes into the middle ear. Unfortunately, not air alone, but at the same time a portion of the contents of nasopharynx, mucus, secretions, and accidental dirt is carried along.

Dr. Haug has had the opportunity to observe a case in which an acute middle-ear inflammation was caused by snuff, as a result of sneezing, and particles of snuff were extracted through the incision in the drum-head. More important for us is the fact that many of the microorganisms which are found in the normal oro-nasopharynx, and are the most exquisite provokers of infectious disease, may be carried along the same path and set up an inflammation, especially when the nasal mucus has lost its bactericidal properties from pathological processes.

This latter condition is necessary, otherwise in spite of the presence of pathogenic organisms no disease will occur. We well know that as a result of the removal of the protective apparatus, as, for instance, paralysis of the ciliated epithelium of the upper respiratory tract from a sudden cold, etc., an infection of the general organism may occur; we know, indeed, that the greater part of the acute general infections do thus occur. Therefore, we are not surprised that the largest portion of the acute inflammations of the ear occur by the way of tubal infection — infection through the blood-stream, as well as infection from without through the external meatus, are far less frequent. “An ounce of prevention is worth a pound of cure.” Having established the fact that infection of the ear can readily occur from the nasopharynx by continuity or contiguity, we should direct all our efforts to prevent this eventuality.

Therefore it is our task to warn our patients against voluntary air-condensation in every acute catarrh, every angina, whether exclusively local or the expression of a general infection. Caution should be exercised in blowing the nose. Never blow the nose with closed mouth or both nostrils closed. Von Tröltsch advises the countryman’s method.

We now come to the proper consideration of the therapeutic employment or non-employment of the air-douche. Haug first must speak of the acute middle-ear inflammations. These processes are associated with more or less marked reduction of hearing power, and since we know that such disturbances are often relatively easily improved by the air-douche, its employment follows quite logically. This was formerly the custom of almost all ear doctors, and is still so to some extent.

May the air-douche be employed in the acute catarrhal or acute purulent middle-ear inflammations? No, repeatedly no! The commonest general surgical principle contraindicates this procedure. “Every inflamed organ should have rest.”
PREVENTIVE TREATMENT OF HEREDITARY SYPHILIS.

Fournier (La Semaine Médicale, Nov. 30, 1898) discusses this question: In the event of pregnancy when the father is syphilitic at the stage when the disease may be transmitted, and when the mother is healthy, can medical art intervene to safeguard the child; and, if so, what is the means to be adopted? He considers two classes of cases: (1) when the pregnancy is the first one, supervening shortly after marriage; (2) when several previous pregnancies have resulted disastrously in abortion or in early death of the child. He maintains that the child can be safeguarded by antisyphilitic treatment of the mother, even when she is healthy. He claims that this treatment is rational, effective for the child, and free from danger to the mother. It is rational, because Porak's experiments have demonstrated that the fetus in utero can be reached by drugs through the placenta. Within forty minutes of the administration of iodide of potassium to the mother Porak found the drug in the urine of the fetus. It is safe for the mother, as demonstrated by wide experience. He quotes Pinard to the effect that he had not yet come across a case where the mother had suffered. As to the efficacy of the treatment, he does not claim that it will invariably save the child either from death or from syphilis. But that it is a safeguard in the great majority of cases is shown by the results, both with first children when the mother is healthy and the father had syphilis in a transmissible stage at the time of marriage, and also when several preceding pregnancies had resulted disastrously. He recites several cases illustrating this point. Even though cases occur with no good results, he maintains that the attempt should be made; to do nothing is to run the risk of doing harm by compromising the child's health; to intervene is to run the risk of doing no good, and it is better to act uselessly than harmfully. The cardinal points of treatment are that it should be begun as soon as possible after the onset of pregnancy, and that mercury is the best drug to administer. It is much superior to iodide of potassium in the prevention of hereditary syphilis; but if the iodide is given in conjunction with mercury, all the better. Inasmuch as it is not an adult but the fetus that is being treated, small doses should be given. The treatment should be continued during the whole time of pregnancy. As to the particular form in which the mercury is given, and as to whether it be given continuously or intermittently, these matters the author thinks may be left to individual discretion and to the idiosyncrasy of the patient.—British Medical Journal, Feb. 25, 1899.

IODINE IN THE TISSUES AFTER THE ADMINISTRATION OF POTASSIUM IODIDE.

An abstract of a paper on this topic appears in the American Journal of Physiology for March, 1899. In it P. A. Levene points out that during the last few years there have been found in various organisms a number of normal tissue constituents containing iodine, as iodocarnein, iodokeratin, iodospingin, iodoproteid, iodofat. Some of these bodies can be obtained synthetically without great difficulty. It was the aim of the author to investigate the tissues of the higher animals as to their power of binding iodine intramolecularly.

For this study hens were employed, since in them the chemical changes of at least one tissue could be followed from day to day. The eggs were examined from time to time during ten weeks, at the end of which period the other tissues were analyzed. During the first three weeks the author found iodine only in the form of potassium or sodium iodide. Beginning with the fourth week the iodine appeared as an organic compound, apparently as iodo-fat. Of the other tissues or organs, the following were examined: nervous tissues, muscular tissues, glandular organs, gastrointestinal tract, skin, and adipose tissue. In none of them could any appreciable amount of organic iodine be detected with the exception of the bones, where a noticeable quantity of iodo-fat was present.

Comparing these results with all that is known on the subject, the author comes to the conclusion that only certain keratins, such as that of the hair, are capable of binding iodine in the organism; only certain proteins, such us that of the thyroid gland, have the same faculty; and only certain fats act in the same way. Whether this result depends on the peculiar chemical composition of those compounds or on a peculiar activity of the different organs or organisms the author will endeavor to solve.

INJECTIONS OF NORMAL SALINE SOLUTION IN DIABETIC COMA.

Roger and Balvay (Lyon Médicale, Jan. 8 and 15, 1899) report the following case: A
man aged twenty was admitted to hospital on June 3, 1898. He had had syphilis and ague, and was addicted to alcohol. Five years before he had remained unconscious for some time after a blow on the head. On July 2 he had several epileptiform fits. Though anasarca was present, there was no discoverable cardiac or renal lesion. The urine contained a quantity of sugar. On July 23 he had a fit, with deviation of the head and eyes to the left, and clonic spasm in the face, chiefly on the left side. On August 1 the edema of the legs extended to the thighs. There was slight left facial paralysis, and the knee-jerks absent. On August 2 complete coma with epileptiform convulsions came on. Urine was scanty and had to be drawn off by a catheter. He was then treated with injections of normal saline solution, and received in all, between August 4 and 9, nearly fourteen pints, three and a half of which was introduced directly into the veins, and the rest subcutaneously. Besides this he had three enemata containing 17½ fluidounces each. By these means free diuresis was established, and the kidneys being sound the poisons were probably flushed out through them. As soon as consciousness returned he ate with avidity, and swallowed large amounts of alkaline water, containing in all nearly ½ ounce of sodium carbonate, which doubtless aided the process. On August 16 his condition was as good as it was before the coma appeared. He lived four months and then died of empyema and phthisis. Post mortem the pancreas was found to be partially absent. Towards the end there was pus in the urine, and calculi were found in the pelvis of the kidney, whose substance was found on microscopical examination to be perfectly healthy. The condition of the brain is not noted.

The authors have been able to collect nineteen cases of diabetic coma treated by saline injections, mostly published in Germany and England; of these only one, a case of Lépine's, recovered from the coma, but few or none appeared to have received such copious injections.

**SUPRARENAL GLAND EXTRACT AS A HEMOSTATIC.**

The *British Medical Journal* of February 25, 1899, contains an article by Lermite upon the use of suprarenal gland. In 1896 Dor, and subsequently Darier, made use of an extract of suprarenal gland in ophthalmic practice. Their object was to reduce hyperemia of the conjunctiva in cases where operation was urgent, but in which, owing to local congestion, it was difficult to obtain anesthesia with cocaine alone. Marked success attended these trials, and suggested its further employment in cases of conjunctivitis, keratitis, and iritis. It was found that a single drop of a watery extract was sufficient to render the bulbar conjunctiva anemic, and under its use, in conjunction with cocaine, iridectomies were performed.

In 1897 Velich confirmed these statements, and affirmed that a watery extract, when dropped into the eye, caused a marked vascular constriction, and so relieved conjunctival hyperemia, however caused. Velich also investigated the action of the suprarenal extract on the vessels lying under the unbroken skin, and found that the normal pink color quickly disappeared under its application. The same vasoconstrictor action was noticed when the extract was applied to eczematous skin, navi, and even sarcomata.

In 1898 J. A. Mullen reported the results he had obtained from the use of suprarenal extract in nasal surgery. He, like his predecessors, made use of it for the purpose of operation only, and claimed for it that it not only prevented primary but also secondary hemorrhage, and increased the anesthetic effect of cocaine to so marked a degree that the cautery could be carried down to the periosseum with the greatest confidence.

In the light of these results Dr. Lermite determined to endeavor to carry the investigations into the hemostatic qualities of suprarenal gland a step further, and to widen the scope of its utility by treating actual hemorrhage with it. A suitable case for this purpose presented itself early in August of last year.

The patient, a boy aged six, was brought to Dr. Lermite with the following history: He had a severe attack of diphtheria in 1894, and during the stage of convalescence had repeated attacks of epistaxis. These had persisted up to that time in spite of every form of treatment adopted. The treatment had been entirely constitutional, not local. For one year before Dr. Lermite saw him he had been taking a mixture containing potassium chlorate three grains and tincture of iron chloride five minimis, three times a day, with more or less persistence, but without any effect in diminishing the bleeding from the nose. These attacks of hemorrhage occurred at all hours of the day and night, often without apparent cause, but sometimes
they followed on any unusual exertion. The attacks varied in intensity and duration, often lasted a considerable time (an hour or longer), and the loss of blood was always great. At times he would have three or four attacks on three successive days, and then would follow an interval of a fortnight without an attack. On the whole, they averaged three or four a week. During the attacks the child was laid prone, and cold compresses, generally of vinegar and water, applied to the forehead.

On examination of the nasal cavities the only abnormality present was a dilated and angiomatosus condition of the vessels. The site of the hemorrhage could not be detected. Constitutionally the boy was in a weak state and had enlarged glands in the neck and right groin, probably tuberculous. The lungs, heart, and kidneys (urine normal) were apparently healthy.

At first Dr. Lermitte ordered a nasal douche containing liquid extract of hamamelis, to be given every night and morning. This was continued for one month without success. On September 17, 1898, he commenced treating the nose locally by inserting into each nostril a pledget of cotton-wool soaked in a five-per-cent solution of cocaine and leaving them in situ for five minutes. On withdrawing these similar pledgets soaked in a saturated solution of boric acid containing five grains of dried extract of suprarenal gland to the ounce were inserted and left in for the same length of time. These applications were made on alternate days till October 7 (three weeks), then on every third day till October 31 (three weeks), and afterwards on every fourth day up to November 22; making in all twenty-four applications.

The immediate result on the nasal mucous membrane was to produce a condition of ischemia, and the effect on the epistaxis was to cause its cessation. Up to the time of writing there have been no attacks of hemorrhage since the first application was made.

That there was no hemorrhagic diathesis present, Dr. Lermitte says he had occasion to prove on November 28, when he removed the enlarged cervical glands. There was nothing more than a very moderate amount of bleeding at the time of the operation and no subsequent oozing, the scar having healed perfectly by the sixth day.

The author hastens to report this case in the hope that others may be induced to use suprarenal gland extract in the treatment of hemorrhage due to various causes, as he says he is led to the conclusion that in this, one of the latest additions to our armamentaria derived from the animal kingdom, we possess a very powerful hemostatic whose use, unlike some others, is attended by no unpleasant effects either at the time of its application or subsequently.

**THE "LANCET" AND QUININE IN MALARIA.**

In a special article upon this subject the Medical News of March 4, 1899, again returns to the question which we have so often discussed in the Therapeutic Gazette in editorials, articles, and progress items. We quote the article simply to present both sides of the matter, willing to let it rest with the profession:

"The London Lancet of February 4, before it had seen our answer, we suspect, comments approvingly on Dr. Hare's criticism in the Medical Record of our position with regard to the use of quinine in malaria, and especially as to its use in blackwater fever, malarial hematuria, or hemoglobinuria. The Lancet considers that Dr. Hare is very sensible in echoing the caution which Koch has lately given with regard to the use of quinine in malarial hematuria, 'a caution, indeed, which had been given before by many writers in America, and especially by many physicians in the States.'

"Our views on the subject have aroused a good deal more attention than we anticipated. We do not pretend to any profound knowledge of the subject gathered from our personal experience. We stated practical conclusions for the benefit of the general practitioner based on the opinions of thoroughly conservative experts in the treatment of malaria.

"We shall now quote more fully the authorities substantiating our position, and ask a candid judgment as to whether it is not the only position possible for an unprejudiced medical editor to hold. Osler in the last edition of his 'Text-book' adds to his article on malaria the following clearly expressive paragraph, which was evidently penned after consideration of the articles called forth by Koch's declarations regarding his experience in South Africa: 'An interesting question is much discussed whether quinine does not cause or at any rate aggravate the hemoglobinuria. We have not yet seen a case in which this condition has occurred as a result of the use of the drug. It seems localized in certain sections, and Bastianelli states that
it is not seen in the Roman malarial fevers. He recommends that in any case of hemoglobinuria if the blood shows parasites quinine should be administered freely. In the postmalarial forms quinine aggravates the attack. In the active malarial infection the patient runs less risk with the quinine.

"In The Lancet of December 24 there is the discussion of a case of malarial hemoglobinuria before the Pathological Society of London. Dr. W. H. Crosse says of his patient: 'In spite of his improving under quinine he had a slight relapse of the hemoglobinuria, which disappeared while he was having still larger doses of quinine.' Dr. Crosse was until recently the chief medical officer to the Royal Niger Company of Central Africa. He has had an extensive experience with malarial hemoglobinuria, including a number of attacks of the disease himself. He discussed this subject at the opening of the medical session at Guy's Hospital last fall (see British Medical Journal) and completely disagreed with Koch. He attributes his own attacks of malaria to his failing to take quinine. He tells the story of a friend who foolishly decided against the use of quinine and suffered a very severe attack, from which he was saved only by the free use of quinine. He insists that his friends going to Central and South Africa shall have no foolish notions with regard to any possible harm produced by quinine during the course of the affection.

"Dr. Moffat, principal medical officer of the Uganda Principality, writes to the British Medical Journal of September 24 as follows: 'Prof. Koch may be right when he says that quinine poisoning causes hemoglobinuria. I do not possess sufficient knowledge to criticize that statement. This much I will say, that after seven years in eastern equatorial Africa, during which time I have treated many hundreds of cases of malaria, I have never seen a man die of fever when quinine was given properly and early in the case. The fatal cases, whether complicated with hemoglobinuria or not, have all been those in which for some reason quinine was not administered, or was given in very small doses, or else resorted to only when the case was practically hopeless. Out of nine cases of blackwater fever which I have had two were fatal; in both the administration of quinine was neglected until too late. All the cases which recovered were treated with heroic doses of quinine, with one exception. In this one case thirty grains of quinine was given in the twenty-four hours, and the attack lasted for days, the hemoglobinuria subsiding gradually. In the other cases 60 to 120 grains in the twenty-four hours was given, and the hemoglobinuria only lasted from twenty-four to thirty-six hours, stopping quite abruptly.'

"Laveran in the last edition of his book on 'Paludism' says: 'It is always necessary to resort to quinine for the treatment of acute paludism when we wish to break up the fever, and especially in grave cases.' Further on he continues: 'The rarity of quinine hemoglobinuria shows that an individual predisposition is necessary for it. Malaria is only an accessory (adjuvant) cause. Sulphate of cinchonidine does not give rise to hemoglobinuria, according to Pampoukis, and ought to be substituted for quinine in patients liable to it.' Laveran, it may be seen, does not feel able, even in patients with an idiosyncrasy, to advise a radical departure from cinchona-bark treatment in some form.

"Next we come to the question of the influence of quinine on the kidneys. The Lancet quotes with approval Professor Hare as saying that according to writers of experience quinine in full doses has similar effects (nephritis, fatal malarial hematuria, and glomerulitis have been mentioned just above, and to all, or at least to some, of these the reference is made): 'These effects are brought about by quinine producing renal congestion and inflammation.' We should like to know some reliable authorities for this startling statement of The Lancet. If full doses of quinine produce renal inflammation, Italy would be overrun with nephritis. So would all the malarial countries. The fact is that nephritis is no more frequent in malarial countries where quinine is used freely than it is elsewhere. Hirsch, the medical geographer, made a special study of this subject years ago, and his conclusions have never been contradicted. The Lancet, unwarrantably it would seem, is lending the weight of its authority to an opinion liable to do a good deal of harm when it states that quinine in therapeutic doses ever produces nephritis except in the rare cases in which idiosyncrasy exists.

"Laveran discusses in his book (before mentioned) the complications to which the use of the salts of quinine may give rise. He mentions toxic symptoms, hemoglobinuria, icterohematuria, cutaneous eruptions, visual and auditory phenomena, and oxytocic properties, but says not a word of nephritis. Rem
THE THERAPEUTIC GAZETTE.

Picci, who made a study of nephritis complicating malaria in Rome, and who has collected the statistics of over 7000 cases of malaria that occurred in the Roman hospitals during the last four years, said in Il Poli-clinico last year: 'The treatment of the kidney affection (of malaria) is the same as that of malaria itself. Quinine, which according to some authors causes albuminuria and hemoglobinuria, is not contraindicated, but on the contrary is indispensable. These symptoms occur with or after the malarial paroxysm and before the employment of quinine; they get worse with every new attack, and disappear with the malaria itself after the energetic use of quinine.'

"We sincerely hope, then, that the omniscient editor who sits up aloft in The Lancet offices and dictates, without quoting his authorities, ex cathedra conservative opinions to an inexperienced medical public, will let us share in the special illumination on this subject vouchsafed to him. The subject is an extremely interesting and important one. Let us have the facts and the figures to demonstrate why we should hesitate to use full therapeutic doses of quinine whenever there is active malaria despite the presence of nephritis, of albuminuria, or of hemoglobinuria. As far as our researches into the literature of the subject go, the authorities, who speak from experience, are on the other side."

THE RESULTS OF 360 OPERATIONS FOR GALL-STONES, WITH SPECIAL REFERENCE TO 151 PERFORMED DURING THE PAST TWO YEARS.

The operations comprise all or nearly all that can be imagined in connection with gall-stones. The mortality of the operation in simple uncomplicated cases was 3.8 per cent. The writer advises early operation before the gall-stones have been forced into the deeper bile passage. In the earlier periods the operation is less dangerous and also less difficult than when the common duct has to be opened. When symptoms of obstruction of the passages are present, he proceeds to operate unless evidence is present of the re-estimation of permeability of the duct. Cure of the cholelithiasis by internal remedies the author looks upon as one of the rarest of events. Development of carcinoma he considers one of the dangers to be feared in cases of long-continued irritation from gall-stones. The normal procedure is cholecystectomy, and although with this recurrence is possible, he has never seen it. Cholecystectomy is a more radical operation, but it is also more difficult and more dangerous. Ideal cholecystectomy can only be exceptionally performed; a free drainage of the gall-bladder is the surest means of overcoming the catarrh that so often exists.—Medical Press and Circular, March 8, 1899.

THE TREATMENT OF UREMIA BY INJECTIONS OF SERUM IN THE RENAL VEIN.

The Medical Press tells us that at the last meeting of the Lyons Medical Society de Lignerolles gave an interesting account of his treatment of uremia by injections of serum into the renal veins. The kidney, he said, possesses an internal secretion which it pours into the organism by means of its efferent vessels. The importance of the antitoxic rôle of that secretion against hurtful substances that the kidney could not eliminate had been demonstrated by numerous experiments and by clinical facts. To remedy that renal insufficiency Brown-Séquard, Meyer, Ajello, and Parascandalo injected in animals deprived of their renal organs the diluted juice of kidney extract; they obtained in uremic troubles very favorable results, which confirmed the clinical observations of Dieulafoy, Teiddier, Donovan, and others. But "would it not be better," asked Brown-Séquard, "to employ the venous blood of different parts of the organism than the extracted juice of these parts? The venous blood coming from an organ contains, in fact, the principles of the internal secretion special to that organ."

This conception, which had already guided Meyer in his experiments on the periodic respiration of Cheyne-Stokes, had been realized by Professor Vitzou, of Bucharest. The remarkable cases of prolonging life which he obtained in animals from which the kidneys had been removed, by injections of defibrinated renal venous blood, encouraged Dr. Turberie to treat in the same way patients suffering from uremia. Under the inspiration of Professor Teissier, the speaker made a special experimental study of the treatment at the hospital.

The blood of the renal vein of a young healthy goat was drawn under perfectly aseptic conditions, and its serum decanted into six-dram bottles. The toxic properties of the serum were insignificant, especially when
the liquid was injected into the subcutaneous cellular tissue.

The cases he presented to the Society were not numerous on account of want of time, but such as they were they merited attention, not only on account of the novelty of the method, but also, and what was more important, by the constancy of the results obtained. The first case was that of acute nephritis complicated with uremia. The patient, a boy of fifteen, entered the hospital suffering from anasarca, the result of scarlatina. The urine contained a large quantity of albumin, leucocytes, and cylinders. Vomiting was persistent. The symptoms became so grave that an injection of six drachms of the serum was made in the right flank. The following morning the improvement was considerable; the violent headache had subsided, as well as the vomiting, and four days afterward the edema had disappeared, while the urine, scanty before the injection, returned with great abundance. All trace of the albumin had disappeared at the end of a fortnight, and the patient rapidly gained strength. Another case was that of a woman aged sixty, who entered the hospital with signs of chronic nephritis (fruit de galop heart, a large quantity of albumin in the urine, diminished renal permeability). An injection of the serum of the renal vein produced a very notable improvement in all the symptoms and in the general condition of the patient. Here also the albumin disappeared.

The details of the following case were furnished to the speaker by Professor Turbure, of Bucharest:

Nicholas V., aged twenty-seven, entered the hospital with generalized anasarca; the legs were swollen to the abdomen, and the patient complained of frequent micturition, thirst, headache, pains in the back, and tingling sensation in the fingers. The lungs, heart, and liver appeared sound. The urine contained albumin, and was very abundant (five liters). In a few days these symptoms grew much worse, the headache became excessively violent, dyspnea set in, and finally he was seized with tonic convulsions, in spite of the application of repeated wet cupping. Neither the quantity nor the quality of the urine could explain these phenomena. What was wanting was the internal secretion of the kidneys, whose office was to neutralize the toxins accumulated in the organism. This point was remedied by injecting under the skin of the patient three drachms of defibrinated renal venous blood drawn from a strong and healthy dog. A few hours later the patient became calm, and asserted that he felt much better. Four days afterwards the headache returned, but yielded to another injection, and the urine diminished by a third. A few days afterwards the patient insisted on having another injection, and in all six were given with constantly improving results, so that at the end of six weeks he left the hospital cured.

In summarizing the effects of the treatment, M. Lignerolles said that the effects of injections of six drachms showed themselves in general a few hours after injection: The violent headache was the first to disappear, while the nervous troubles, prostration, weakness, melancholy, delirium, gave place rapidly to sometimes exuberant gaiety. The vomiting ceased after one injection, and the oppression or dyspnea was eased in a very short time, while the urine, scanty before the injection, became very abundant under its influence, with consequent removal of the edema.

From all these facts he would conclude that injections of the serum of the renal vein could be employed with success against the uremic complications of nephritis, and could contribute to the improvement of these maladies, as he had several times observed. They furnished to the organism the internal secretion wanting, and allowed the kidney to recommence its normal function of excretion and its antitoxic rôle.

---

**INTRAVENOUS SALINE INJECTION IN SEVERE HEMORRHAGE.**

As a result of an experimental research Cobb tells us in the *New York Medical Journal* of January 28, 1899, that in using saline injections it is not necessary to take accurately the temperature of the saline solution, if one is in a hurry. [With this we entirely disagree.—Ed.]

If the solution feels comfortably warm to the finger no harm will result from its introduction. The temperature should be about 114°F., but if it is 125°F. do not lose time in cooling it. [We think it should be 105°. —Ed.]

It is astonishing that no apparent harm resulted from the introduction of saline solution at the extremely high temperature of 130°F. One would naturally believe that such a temperature would coagulate the albumin and seriously damage the red cells.

Saline given with oxygen will save almost hopeless hemorrhage cases.
Do not lose time in getting the solution into the circulation.

It is urged that the solution be introduced into a vein, after a severe hemorrhage, in preference to the slow method of subcutaneous injection.

To furnish as much blood as possible for the purpose of carrying oxygen, bandage tightly the extremities, thus forcing the blood in the capillaries back to the heart. The introduction of small quantities of air into the circulation seems to make no particular difference, for undoubtedly air was introduced into the circulation of all the dogs in these experiments.

All dogs urinated after the pressure had been reinstated by the saline solution. The question of overdistention of the heart must not be ignored by introducing too much saline, for the pulsations become "running" when there is an excess of solution. So far as he could tell, the dogs that recovered urinated more frequently, and passed a greater quantity of water than normal, for thirty-six hours after the operation.

Do not let the patient die while the solution is being sterilized. Be prepared for such emergencies; if not, introduce the solution without sterilization, if the case is urgent. [But only under the skin.—Ed.]

If one does not have time to weigh the salt, take a tablespoonful and toss it into two pints of water. [Two teaspoonfuls would be better.—Ed.]

It is an easy matter to be prepared for an immediate saline injection, for Parke, Davis & Co. are now preparing sterile normal saline solution, put up in ounce bottles, which, added to the necessary amount of water from the hydrant, kettle, or sterilizer, makes the solution ready for instant use.

From these experiments one is led to believe that in opium poisoning it would be advisable to withdraw five hundred cubic centimeters of blood and introduce five hundred cubic centimeters of saline solution.

In the early stages of pneumonia it seems reasonable to believe that the withdrawal of blood, and replacing it with normal saline solution, would relieve the tension of the pulmonary circulation in the early stages, and would furnish a fluid which would more readily take up oxygen.

The blood count was made with the hematokrit, and the hemoglobin tests were made with von Fleischel's hemometer. The tests, of course, are only approximately correct.

The blood counts and hemoglobin tests showed great variations, probably due to the fact that some of the dogs had been kept in the pound until they were sick.

Saline solution and oxygen in uremic convulsions or threatened eclampsia have already been proved the most efficacious treatment for these terrible complications.

THE EMPLOYMENT OF SALINE SOLUTION.

At the Société de Thérapeutique Professor Bologna read a paper on the above subject, which was very exhaustive. In referring to the methods employed, he said that artificial serum could be introduced into the organism by four ways—the serous, vascular, subcutaneous, and intestinal.

Intraperitoneal injections were first proposed by Ponfick, who had remarked that the blood effused into the serous membranes was rapidly absorbed. The injections were nearly always made into the peritoneum by means of an incision made above the umbilicus and penetrating to the linea alba; the needle was pushed as in the operation of tapping for ascites. Perforation of the intestine, which many feared, was rare, but the operation was always painful, and followed by distention of the abdomen. As the slightest failure in antisepctic precautions could produce mortal peritonitis, intraperitoneal transfusion was but little practiced.

Intravascular injections were first employed by Huetcr, Roux (Lausanne), and Kummel. The vessels chosen were the veins of the bend of the elbow, or the internal saphena vein over the ankle, which passing over the bone is more easy to discover in stout people, and whose caliber is larger than any of those at the bend of the elbow, while the introduction of air at such a distant point from the heart presents but little danger. The quantity of liquid injected varied between one to three liters, with an average of two liters, at a temperature of 86° F. The rapidity of the current should not exceed ten minutes per liter.

Venous injections present certain inconveniences not entirely exempt from danger. Consequently, many practitioners prefer for these reasons the subcutaneous method. For inexperienced hands the venous injection is a regular operation; the veins are frequently difficult to discover; timid operators are afraid of introducing air into the veins; and in any case septic accidents might be provoked, such as phlebitis. Pozzi published
one case of acute edema of the lungs as a consequence of the operation. Further, the counter-indications, cardiac lesions, and weakness of the myocardium in particular, were more frequent. Bosc, of Montpellier, preceded the injection of the serum by drawing off a liter of blood; while Barré invented a rather complicated apparatus to combine these two operations, so that the amount of blood withdrawn was replaced by its exact equivalent of artificial serum; but there was no necessity of being so precise, as the same effect could be produced by ordinary blood-letting and the introduction of the serum subcutaneously.

The subcutaneous method is at present the most frequently employed, and answers every purpose except in urgent cases requiring the intravenous method. The region chosen should be that rich in cellular tissue, such as the axilla, the abdomen, the thigh, or the gluteal region.

The instruments employed to make these injections are numerous, and vary from that of Dumouthier to the simple funnel, but the simplest for all intents and purposes is the ordinary aspirator of Potain, possessed by every practitioner.

The only trouble arising from the subcutaneous method was the pain from the introduction of the needle, which, however, was insignificant, and that produced by the distention of the skin; or, again, the formation of an abscess, but this latter can be avoided with a little care.

Enemata of salt water were known and employed for a very long time, but it is only within the last two years that this method was substituted for the subcutaneous injections. All know the facility and rapidity of rectal and intestinal absorption for medicated solutions, and no one is astonished at the extreme rapidity by which enemata of salt water are absorbed. These enemata strengthen the pulse, render the urine abundant, and suppress thirst. They are used by Eitz with great success for uremia, and by Boulangier for postpartum hemorrhage and for intestinal hemorrhage in typhoid fever.

In affections of the nervous system, Professor Grasset, of Montpellier, advised saline injections in apoplexy with arterial hypotension. They were proposed in contagious affections such as erysipelas, measles, scarlatina, smallpox; while Professor Tommassi, of Palermo, in certain skin diseases derived benefit from them, especially in chronic eczema, and in lichen attended with great itching. His colleague, Barbier, obtained considerable success with the saline injections in infantile cholera, and generally in all the intestinal affections of infants.

Lancereaux published remarkable effects of subcutaneous injections of a saline gelatin solution in cases of aneurisms (gelatin one drachm, saline solution ten ounces). Injected under the skin of the gluteal region, and renewed once or twice a week, ten to twenty injections were generally sufficient to effect a cure.

Among the contraindications of the treatment by saline solutions he would mention heart affections, edema of cardiac origin, dropsies, pulmonary congestive lesions, and renal sclerosis.—Medical Press and Circular, March 8, 1899.

---

**ON THE ABSORPTION OF IRON.**

The Boston Medical and Surgical Journal of March 2, 1899, contains an article by Austin upon this subject. After detailing his research he adds his conclusions, which are as follows:

If the difference between the amount of iron ingested and the amount eliminated represents the amount retained in the body and hence absorbed, then there can be no question from these experiments in regard to the absorption of the iron of the blood when taken either in the form of hemoglobin, as in the meat, or as hematin in the preparation used. This assumption also appears as fully justified as that the amount of nitrogen in albuminous food taken less the amount of nitrogen in the feces and urine represents the amount of the same element taken on by the body in the form of tissue, and this principle has been assumed as proven by all physiologists who have been engaged in experiments on metamorphosis. This also substantiates the views held by Kebert in regard to the absorption of the blood. Considering that the amount of iron retained in the third period from the meat was proportionally as great as in the second, then the amount of iron retained from the .2058 gramme contained in the hematin preparation must have been at least .0152 gramme, or 7.30 per cent—a very small portion, it is true, but it does not indicate necessarily the total amount absorbed. In applying the same calculation to the beagle we would find that out of .0774 gramme in the albuminate at least .0026 gramme, or 3.3 per cent, was retained; her—
we cannot from this say absolutely that iron albuminate is not absorbed, but that the amount retained is only one-half of that in the hematin; of the ferrous sulphate it is quite evident in this experiment that none was retained, and hence probably none absorbed. A brief summary of this work will establish the following points:

1. That iron is constantly being eliminated both in urine and feces during fasting.
2. That apparently raw meat furnishes an available form of iron for absorption under normal conditions.
3. That inorganic iron as represented by ferrous sulphate is non-absorbable.
4. That albuminates and peptonates of iron are absorbable, but to a limited extent.
5. That organic iron, of which hematin and hemoglobin are representatives, furnishes the most easily absorbable and most valuable of all iron preparations.

A NOTE ON THE TREATMENT OF TUBERCULOSIS AT FALKENSTEIN.

The sanatorium is situated at a height of 1300 feet on the southern slope of the Taunus mountains; it faces the southeast, where the ground falls some thousand feet to the valley of the Main, and to Frankfort, and is protected on the three other sides by the higher portions of the Taunus range. The climate is cold in winter, but although there are fogs the atmosphere is singularly free from winds and dust, and there is no perceptible fall of temperature at sunset.

The main building is in plan like a wide horseshoe and encloses a gravel terrace, along which extend covered verandas. In these cane sofas or deck chairs are ranged, and on these the patients spend practically the entire day.

Additional pavilions are placed in the grounds; some of these revolve so that they may be turned to avoid the wind and catch the sun; the Germans have, with somewhat grim humor, christened the pavilions by such names as “The Hall of Sighs,” “The Temple of Bacilli,” etc.

For the first few days the patients only lie out from after the second breakfast to 5 P.M., but afterwards the day’s routine is as follows: After ten minutes’ rubbing by the attendants the patients assemble at early breakfast, which in summer is from 7 to 8 and in winter from 7.30 to 8.30; this consists of coffee, rolls, and butter, and in addition hot or cold milk ad libitum, the watchful attendant at once replenishing empty glasses. Then the balcony is sought, and the patients lie down, placing their feet in fur bags, and wrapping rugs and shawls about them. The wraps belong to the patients and must be provided as part of their outfit. The most expert of packers then goes round and rapidly and skilfully tucks in the patients, who then appear like symmetrical and well-cared-for mummies.

At ten o’clock they go in for second breakfast, which consists of rolls and butter, and hot or cold milk ad libitum; to those who in the opinion of the medical attendant need it, strengthening soup is served. They again lie on the veranda until they go in for dinner at 1 P.M. This and supper are of the kind usually served in German hotels, but special attention is paid to making each course as nourishing as possible, and each meal commences with one of the thick nourishing soups that form a Falkenstein specialty.

At 4 P.M. milk is brought round the veranda; this, as well as the 9 P.M. milk, is not included in the regular tariff, but is served at a cost of one penny per glass.

All the milk used at the sanatorium comes from the dairy of the establishment, which is situated on the hillside above, and is sterilized. For those who cannot digest so much milk kumiss is provided.

The patients are encouraged to drink plenty of milk, and generally take from six to eight tumblers a day, which is a large amount for people who are taking daily four solid meals. Occasionally the amount of milk has been limited, as lately happened to a homesick American who tried to expedite his cure by drinking fifteen glasses a day. Supper is served at 7 P.M., and after it the patients may lie out to 9 or 9.30 P.M. At 9 P.M. milk is served round. The patients then retire to their bedrooms, which are warmed by pipes; the windows, however, are left open during the night.

When the patients arrive they are thoroughly overhauled by the entire medical staff; this is repeated monthly, a daily inspection being made by one of the resident medical men. Their temperatures are taken four times daily—at rising, noon, 4 P.M., and night. If the temperature shows fluctuation it is taken eight times daily. It is interesting to see how, when the clock strikes twelve and four, all the recumbent patients pull out their thermometers and place them in their mouths until they are ready to be entered on the charts. These hours are anxious ones to
those with a temperature tending to run above normal, as the penalty for raised temperature is banishment to the bedroom until it again becomes normal.

The sanitation of Falkenstein is excellent; there is an abundant water-supply from pure springs situated higher up the mountains, and the sewage is received in precipitation tanks. The whole place is kept scrupulously clean, and constant war is waged on dust.

Although the sanatorium is surrounded by extensive woods with tempting walks, they are out of bounds for the majority of patients, who are required to rest as much as possible; indeed, even needlework is practically prohibited, and letter-writing is discouraged. It is only when patients are nearly well and about to leave that they are allowed to take walking exercise, and even then the distances allowed are short, and the limits fixed are strictly observed.

It will be seen from the above that rest, air, and food are the three means of cure, and that these are administered with no stinting hand. Complete physical idleness, twelve hours in the open air, the night spent in a room with open windows, and frequent full meals of nutritious foods, with plenty of milk in between, take the place of medicines. It is wonderful how the treatment agrees with the patients, how the long exposure to the fresh air does not cause cold, and how the frequent meals are awaited with sharp-set appetite. Of the benefit of the treatment in the majority of cases there can be no doubt, and that not only in incipient cases, but even when both lungs are affected.—Medical Press and Circular, March 8, 1899.

THE RADICAL TREATMENT OF SIMPLE ULCER OF THE STOMACH.

Tricomi (Revue de Chirurgie, Feb. 10, 1899) has operated upon twenty-one cases of simple ulcer of the stomach with but a single death. He holds that the indications for operation are recurrence of ulceration with marked deterioration of general health, resistance to medical treatment followed scrupulously for a long period, intense pain, especially when accompanied by obstinate vomiting, recurrent hematemesis, and evacuating cachexia, gastric dilatation, the formation of a palpable tumor, and the development of an extensive adhesive peritonitis. As an operation of choice, the author prefers gastroenterostomy. This, he holds, is applicable in all cases, no matter what may be the state of the lesion.

The loss of resistance incident to this procedure, and consequently the comparatively short period of time during which the food and the gastric juices remain in the stomach, is the probable cause for the cure which takes place. Of the author's twenty-one cases, one died of acute peritonitis in a day and a half; another died after a month from interstitial occlusion. Tricomi contrasts the mortality of some fifty operative cases (ten per cent) with that of the cases treated by medical means exclusively (31.8 per cent), drawing therefrom the conclusion that the operation is one which if practiced early would save about twenty-eight cases in the hundred.

ICHTHYOL IN THE TREATMENT OF ANAL FISSURE.

Conitzer (Münchener Medicinische Wochenschrift, No. 3, 1899) holds that ichthylol is particularly serviceable in the treatment of anal fissure. The applications are repeated twice daily at first, cocaine being employed to diminish the pain. The pure preparation is used towards the end of treatment. A cure results in a few days.

THE TREATMENT IN ACUTE OTITIS MEDIA.

Jones (Liverpool Medico-Chirurgical Journal, January, 1899) writes upon the subject of acute suppurative otitis and its complications, believing that this affection has been somewhat neglected in favor of the chronic form of disease. The first proposition is that once the wall of a great sinus or the dura has been penetrated, there can be no certainty of a successful issue to operative treatment. With the object of proving this proposition he has recorded seven cases which died in spite of operation. The mortality in complicated mid-ear diseases, even when correctly diagnosed and operated upon, is still high. Even when immediate recovery takes place there is likely to be subsequent alteration of brain function.

The author's second proposition is that while operations for the relief of extradural complications of suppurative otitis—i.e., extradural abscess, commencing phlebitis, mastoid abscess, cervical abscess, etc.—have been invariably successful as far as the complication itself is concerned, these operations, and the radical operations for simple chronic suppurative otitis, have not always resulted in cessation of the discharge, nor in restoration of the hearing power.
Stacke reports, as a result of his radical operation, six per cent of continued discharge and twenty per cent of relapses. Statements such as "completely cured" must be taken with caution unless several years have elapsed since the operation. In spite of the great advance made in recent years in the surgical treatment of chronic suppurative otitis and its complications, the success attained is not such as to excuse any slackening of our efforts in preventing acute cases from becoming chronic.

The author's third proposition is, that with the exception of tubercular cases—and even this is a doubtful exception—all cases of chronic suppurative otitis have once been cases of acute or subacute otitis media, and many of them non-suppurative otitis; and further, that the majority of these cases, by appropriate treatment during the acute stage, might have been prevented from becoming chronic.

Another and stronger reason for directing attention to the acute state is that grave intracranial complications may and often do arise during the acute stage of suppurative otitis. During the first stage of acute otitis media, before the membrana tympani has perforated, the fluid within the ear is serous or serosanguineous and may become absorbed without any further development. The local treatment consists in the application to regions below or in front of the ear of the cold Lieter's coil, and the rendering of the external canal as far as possible aseptic. So long as the pain is not severe and there are no indications of pus formation within the tympanum, paracentesis of the membrana should be deferred. As soon as pus begins to form, the membrane, if not already ruptured, should be punctured, the pus blown out or aspirated, and suitable antiseptic measures resorted to. There is after this operation an immediate improvement in all symptoms, temperature running down, and the symptoms of meningitis, if present, disappearing. These cases are subject to relapse, and should be kept under observation for several weeks. Probably the accessory cavities of the tympanum share in the inflammatory process in the majority of cases. Resolution often takes place. If, however, the attic or antrum becomes cut off from the tympanum, or the contributory cells are cut off from the antrum, so that the inflammatory products do not escape, acute constitutional disturbance will follow, and hence prompt operation is indicated, and the results of this are highly satisfactory. After subsidence of the acute symptoms, if, combined with the free discharge from the ear and the relief of pain, there is tenderness on pressure or tapping on the base or apex of the mastoid; if the apex feels to be slightly prolonged on the affected side; if there is a slight cushiony feel on one side as compared with the other; if there is increased heat; if on rubbing the skin briskly on both sides, one side seems a dusker red; if there is pain or stiffness on moving the head from side to side, with rigidity of the sternomastoid; if several or all of these signs are present, an exploration of the mastoid cells is necessary, and in at least four out of five such cases pus will be found.

The operation required is simple opening of the cells down to the extreme tip, and in some cases the mastoid antrum. The wound should be kept open by iodoform gauze packing until the septic processes have ceased. The discharge generally stops at once, the membrane heals, and the hearing is entirely restored.

Jones advocates opening the antrum in every case in which, the acute stage having passed over, the discharge continues. This he believes would frequently prevent caries of the ossicles and the walls of the tympanum, save the patient infinite discomfort, and likewise avoid the necessity for radical operation in after years.

The etiological importance of postnasal adenoid vegetations, or of permanent perforations of the membrana tympani, in causing relapses or continuous suppuration must not be neglected.

THE OPERATIVE TREATMENT OF TYPHOID PERFORATION OF THE INTESTINE.

Platt (The Lancet, Feb. 25, 1899) notes that on the whole it may be said that the results of operation for the relief of typhoid perforation have improved during recent years. From time to time the published cases have been collected and analyzed by Van Hook, Abbe, Monod, Finney, Gesselewitsch and Wanach, and Keen. Keen in January, 1899, collected eighty-three cases with sixteen recoveries. To his list Platt adds three cases of his own and seventeen published by others, giving a total of 103 cases with twenty-one recoveries. Platt's cases are as follow:

A man aged thirty-seven years was admitted to the Monsall Fever Hospital, Man-
chester, at midnight on November 15, 1898, suffering from an apparently mild attack of enteric fever. The temperature was 102° F.; the tongue was moist and coated, the abdomen was fairly soft, there were a few rose spots, the spleen was a little enlarged to percussion but was not felt, and numerous rhonchi were to be heard on auscultation of the lungs. Widal's test gave a positive reaction. On the next day, at 8 P.M., the patient complained of sharp shooting pains below and to the right of the umbilicus; two hours later the temperature rose to 104.6°. On the 17th, at 11 A.M., the patient vomited once. The abdomen was hard and distended, the tongue was dry, and the bowels were constipated. The pulse was 96 per minute, regular, of good volume, but slightly dicrotic. At 1 P.M. the liver dulness had disappeared and perforation was diagnosed. Twenty-two hours after the onset of the perforation the patient was operated upon. An incision four inches long in the right semilunar line was made. On opening the peritoneum there was an escape of gas, followed by a little feculent fluid; the intestines were greatly distended. It was necessary to eventrate a considerable portion of the small intestine before the perforation could be discovered. The perforation was about a quarter of an inch in length and was situated opposite the mesenteric attachment in a loop of ileum lying near the pelvic brim; its distance from the cæcum was not ascertained. The neighboring coils of intestine were covered by a fair amount of dirty fibrinous lymph. There was evidence of several other ulcers in the intestine. The edges of the perforation were turned inwards and the peritoneal surfaces were united by a continuous silk suture introduced by an ordinary sewing needle. Considerable trouble was experienced in returning the intestines to the abdomen because of their great distention. The eventrated intestines and also the peritoneal cavity were irrigated freely with hot saline solution. A rubber drainage-tube was introduced, passing down towards the pelvis, and the rest of the wound was sutured. The operation lasted fifty minutes. On the 18th and 19th the patient was fairly comfortable. The temperature varied between 98.4° and 99.8°; the discharge from the wound consisted of a little thin, yellow, slightly opalescent serum. On the 20th the abdomen was greatly distended, the tongue was dry, and there was retching and slight sickness. Some relief was obtained from an enema containing turpentine. From this date the patient progressed favorably until December 2, when there was a relapse of the fever, which lasted for three weeks. The drainage-tube was removed November 30 and gauze packing was substituted. The wound was healed on December 26.

The second patient was a male, aged seventeen years, whose illness commenced on October 22, 1898. On November 20, eighteen hours after perforation, an incision four inches long was made in the right semilunar line. There was gas and feces in the abdomen; the intestines were not much distended. The perforation was found at once in a loop of ileum passing from the iliac fossa into the pelvis; it was situated near the pelvic brim. An attempt was made to close the opening by a continuous suture, but the bowel wall was so rotten that some of the loops cut out. With some difficulty the opening was closed by interrupted Lembert sutures, its edges being turned inward. The abdomen was washed out with hot saline solution, a drainage-tube from the wound into the pelvis was inserted, and the rest of the wound was sutured. The operation lasted forty minutes. After the operation the patient was much collapsed, and about half an hour afterward two pints of saline fluid was infused into the median basilic vein. He rallied somewhat for a time, but died at 7:15 P.M. on the same day, eight and a half hours after the completion of the operation. The necropsy showed general peritonitis, six or seven other ulcers in the ileum, and the perforation to be situated nine inches from the cæcum. The sutures were sound and the perforation was healed.

The third patient was a man aged twenty-two years. Illness commenced on November 1, 1898. On November 20, nineteen hours after perforation, an incision four inches long was made in the right semilunar line. There was gas and about a pint of feculent fluid in the abdomen; the intestines were not much distended. The perforation was easily found in a loop of ileum situated near the pelvic brim; its edges were turned inward and interrupted Lembert sutures were applied. The abdomen was well flushed out with warm salt solution, a drainage-tube was inserted into the pelvis, and the rest of the wound was sutured. The operation lasted forty-five minutes. The patient rallied for a time, but then sank, and died on November 22 at 11:50 P.M.

Operation for typhoid perforation of the intestine has already given a gratifyin
amount of success. If undertaken within twenty-four hours of the giving way of the bowel a recovery rate of from twenty-five to thirty per cent may confidently be expected, and when it is considered that without operation the condition is almost inevitably fatal, there can no longer be any doubt as to the advisability of the procedure.

MODERN LITHOTOMY.

Loumeau (Annales de la Polyclinique de Bordeaux, March, 1899) apparently on the basis of a single case announces that modern lithotomy implies an elaborate and prolonged crushing, pushed almost to the point of complete pulverization; chloroform anesthesia maintained at the first stage during the period of preliminary washing and crushing, then pushed to the third stage of complete anesthesia during the period of aspiration; rigorous asepsis during the operative act; and finally, postoperative cystoscopic verification as to the complete emptiness of the bladder.

THE TREATMENT OF PAINFUL CYSTITIS.

Albarran (Annales des Maladies des Organes Génilo-Urinaires, February, 1899), following Guyon, characterizes under the heading of painful cystitis a number of affections of different etiology, characterized by their severity of pain, their chronicity, and their persistence in spite of treatment. Because of increased facilities afforded by modern medicine in the examination of the bladder, these painful cystites (at least a great majority of them) have had additional light thrown upon them.

Cystitis due to foreign bodies or calculus, neoplastic cystitis or tuberculous cystitis, are not included in this classification, although they are extremely painful, are chronic, and resist treatment.

It occasionally happens, for reasons quite unrecognized, that an attack of cystitis acquires an extraordinary intensity and obstinately resists treatment. The cause of this cystitis is often a very ordinary one. It may be gonorrhea, or the passage of the catheter, or a vesical infection secondary to grippe. The ordinary microorganisms are the colon bacilli, staphylococcus, the proteus of Heuser, the streptococcus or gonococcus. One or several of these microbes will be found.

The lesions of these painful cystites are usually deep, attacking the submucous layers or even the musculature of the bladder, often even reaching the perivesical tissues. It is very rare in these chronic painful cases to find the lesion purely superficial. The position of the lesions is especially characteristic, since this is always at or near the neck of the bladder. The lesions observed through the cystoscope are usually those common to severe cystitis. Occasionally vegetating cystitis is noted, or even ulcers or leucoplacia. Sometimes one or more ulcers are found on an apparently almost healthy mucous membrane. Pseudomembrane is by no means uncommon. The diagnosis of the anatomical condition is often extremely difficult. Often it is quite impossible to use the cystoscope.

The most serviceable treatment to begin with is that by instillation, either with silver nitrate or weak bichloride lotion or guaiacol oil. The patient should then be given a warm bath, after which one-half to one drachm of a two-per-cent solution of cocaine should be injected, so that it passes over the trigonum and the neck of the bladder. This is allowed to remain in the bladder for five minutes, after which a lotion of boric acid or antipyrin, at blood heat, is gently injected, when the cystoscope may be used. When this local anesthesia is impossible, because of the intense sensitiveness of the bladder, a general anesthetic should be given. This cystoscopic examination should immediately precede an operation, which is nearly always required. Renal infection very commonly accompanies these cases of painful cystitis, a fact which must be borne in mind in directing treatment.

The instillation with which the conservative treatment always begins should be no larger than thirty drops at the most, and of a one-to a five-per-cent solution of silver nitrate. When the bladder is fairly retentive one-half drachm to a drachm of 1-to-5000 sublimate solution may be used. Silver nitrate is usually the most useful application. Before these instillations the bladder should be entirely emptied; since painful cystitis is usually complicated by some degree of retention the complete emptying is usually accomplished only by means of a catheter.

Usually this local conservative treatment fails, in which case surgical treatment is indicated. Curettage of the bladder is a simple procedure, giving excellent results in some cases. It is most applicable in women, since it can be practiced through the urethra. In men the preliminary perineal operation is necessary. This curettage is especially ser-
viceable when the lesions are limited to the region of the neck of the bladder. It should always be followed by careful after treatment, and will succeed in uncomplicated cases. Dilatation of the cervical neck is usually unsuccessful. Fistulization of the bladder is one of the most valuable therapeutic resources; the pain ceases promptly, and the deepest lesions get well when the drainage is sufficiently long continued. In woman this fistulization is made into the vagina; in man the opening should be suprapubic. It allows the surgeon at the time of operation to explore the bladder thoroughly, and to curette or apply the thermocautery, in case these remedies are needed. After drainage the bladder should be thoroughly washed and treated, and the opening closed when the inflammation is cured.

PROSTATECTOMY.

Syms (Annals of Surgery, March, 1899) notes that prostatectomy is essentially an operation of modern date, and there are in vogue at present several methods which have proven fairly satisfactory so far; but the operation is still in a process of evolution, and undoubtedly the best possible results have not yet been attained. The principal methods which are at present employed are as follows:

1. Suprapubic prostatectomy without perineal drainage (McGill).
2. Suprapubic postectomy with perineal drainage (Fuller).
3. Suprapubic prostatectomy, combined with perineal section and drainage (Belfield).
4. Perineal prostatectomy by extensive dissection (Zuckerkanl, von Dittel).
5. Posterior prostatectomy by the sacral route (Rydygier).
6. Perineal prostatectomy, combined with suprapubic cystotomy, without perineal drainage (Nichol).
7. Perineal prostatectomy, combined with suprapubic cystotomy, with perineal drainage (Alexander).

The first three methods, in which the prostate is removed by the suprapubic route, are, in the main, dependent upon the same general principles, but have sufficient variations to mark them as distinct operations. They depend upon opening the bladder suprapubically, then making an incision in the floor of the bladder so as to reach the prostate, and then its removal by enucleation or by morcellation. While these methods have been productive of fairly good results, they are open to certain serious objections, one of the principal of which is the fact that the floor of the bladder is more or less extensively wounded; that the cavity from which the prostate is removed becomes at once part of the bladder pouch, and is thereby a dependent receptacle for urine and exudates, thus rendering infection not only possible, but probable. This objection is not overcome when perineal drainage is resorted to, because the pouch still remains below the level of the tube within the bladder.

Perineal prostatectomy, performed by extensive anatomical dissection, as devised by Zuckerkanl, Dittel, Rydygier, and others, may be excellent from the anatomical standpoint, and is of undoubted use in the treatment of some cases where a very large tumor is present, but it has for its objection the fact that the operation usually is an extensive one, and that it must necessarily be more prolonged than by some other methods, which are serious elements against success in old and enfeebled patients, and also the fact that it does not afford the bladder the advantage of immediate and complete drainage, which is usually essential to the best results.

Perineal prostatectomy, combined with suprapubic cystotomy with perineal drainage, as devised by Alexander, is the best method so far practiced. It is simple of performance, and is dependent upon very proper surgical principles, for the floor of the bladder is not wounded, the perineum is cut in the median line by a single incision, so that the least possible time is consumed and the smallest amount of hemorrhage is encountered. The drainage of the bladder is in the line of gravitation, and the space from which the prostate is removed is not in immediate communication with the bladder cavity, and has perfect and direct drainage, while the urethra is not permanently damaged. In accordance with Alexander's description of this method it is performed as follows:

The patient is prepared for operation by proper emptying of the bowels and by as thorough a cleansing of the bladder as possible. The patient is anesthetized, the bladder emptied, and then distended with borax solution, from eight to ten ounces being sufficient, in most cases, to bring the organ well above the pubes. The rectal bag is not employed. The bladder is exposed by a vertical incision between the recti muscles, and two retraction sutures are introduced through it. Wall. Between these an opening is made into the bladder large enough to
allow the operator to insert two fingers. The bladder and the projecting portions of the prostate can then be thoroughly examined. With the suprapubic opening properly protected the patient is put in the lithotomy position. A broad, median-grooved staff is passed into the bladder through the urethra, and held by an assistant. The membranous urethra is then opened by a median perineal section, the floor of the urethra being thoroughly cut from just behind the bulb back to the apex of the prostate. The staff is then removed. With two fingers of the left hand passed through the suprapubic opening into the bladder, the prostate is now forced well down into the perineum. With the forefinger of the right hand the surgeon begins enucleation, which is performed entirely through the perineal opening. The fibrous sheath of the prostate, covering its posterior and anterior surfaces, is broken into by the finger, the capsule is entered, and the entire prostate shelled out from within its sheath by digital dissection. The inferior and posterior surfaces of the prostate should first be separated from the capsule. The mucous membrane of the bladder and prostatic urethra covering the enlargement, with the underlying muscular tissue, is stripped up from the part to be removed, but is not opened. The lateral lobes are first removed, after which, if there is a middle enlargement or projecting tumor or tumors, these can be pressed downward into the perineal wound and enucleated in the same manner. During the enucleation an assistant can aid materially by drawing the prostate down into the perineum by means of a proper pair of forceps. After the removal of all prostatic growth the bladder and the perineal wound are cleansed by suitable irrigation. A perineal tube is inserted into the bladder through the opening in the membranous urethra. A rubber drainage-tube of moderate size is placed in the bladder above the pubes. The retraction sutures are removed and the bladder is allowed to drop back behind the pubes. The upper part of the suprapubic wound is then closed by sutures and a dressing of gauze pads applied, which is perforated to permit the drainage-tube to pass.

The perineal wound is dressed as after perineal section. The after-treatment consists in daily washing the bladder, the fluid being injected into the suprapubic tube. The suprapubic tube is removed on the fourth day and the lower tube three days later, after which the bladder is washed by a catheter passed through the perineum. A full-sized sound is passed at the end of the second week, and every five days until the perineal opening closes. Both wounds have usually healed in the course of five weeks.

Syms proposes the following modification of this operation, namely, that a laparotomy should be performed, entering the peritoneum just above the vesical fold, by an incision large enough to permit the operator with one hand to press the enlarged prostate well into the perineum without opening the bladder; the rest of the operation to be performed in the manner already described.

With our present methods this would add but little to the shock of the operation, and, if successful, it would detract very much from the dangers following the operation, for the abdominal wound would, of course, be closed immediately, and the treatment of the case would be but little more than the treatment of any ordinary case of perineal section. The abdominal wound should close primarily, and, being small, should permit the patient to soon be got out of bed.

Irrigation and drainage of the bladder may be satisfactorily and easily accomplished from the perineal opening, and the ultimate convalescence of these patients should be much shorter than when the suprapubic opening exists.

A STUDY IN THE TREATMENT OF ACUTE GONORRHEA.

Swinburne (Journal of Cutaneous and Genito-Urinary Diseases) states that the treatment pursued is as follows: The anterior urethra is thoroughly flushed out with a hot solution of potassium permanganate (1:4000), the temperature ranging from 110° to 115° F., and in some cases even to 120° F., always flushing it inch by inch by grasping the penis between finger and thumb at each point until the furthest point that can be grasped is reached; then only is the fluid allowed to pass back to the cut-off muscle. If the anterior urethra only is involved, the anterior urethra only is irrigated; then the patient lies on a table, and the urethra is gently filled to distention with a two-per-cent solution of protargol by means of the ordinary urethral syringe. The patient grasps the glans as close to the meatus as possible, holding it for about ten minutes. The meatus is then closed with absorbent cotton and gauze bandage, which is thrown away at the next urination. When a patient is receiving his first irrigation he must be carefully watched and immediately
made to lie down to receive the injection. This is done to avoid as far as possible the faintness which may accompany the first treatment.

If the posterior urethra becomes involved the treatment differs somewhat in the different cases. Those who readily learn to relax the sphincter, allowing the bladder to fill from the meatus, are generally irrigated in this way, emptying the bladder immediately. If they do not readily learn this, after the interior injection with the protargol has been made, a soft-rubber catheter, sterilized, 12 to 16 F., having the eye near the tip, is lubricated with glycerin or lubrichondrin and gently passed down the urethra to a point just entering the posterior urethra, and half an ounce of a two-per-cent solution of protargol is slowly injected through it, which the patient immediately urinates out. In some cases it is important to see that the bladder is empty; then the catheter is passed into the bladder, the urine allowed to flow out, and one-half ounce of the protargol injected into the bladder. Then, as the catheter is gently withdrawn, more of the solution is injected through the catheter during its withdrawal. The passing of the catheter thus into the bladder is only done in certain cases where it is evident that the patient does not completely empty his bladder, and in certain chronic cases, but as a routine treatment in acute posterior urethritis it is to be condemned. An important suggestion at this point is that the catheter should not be used while an inflammatory condition of the anterior urethra exists, unless the symptoms in the posterior urethra are of such a degree as to call for immediate treatment; a few days' wait may prove better as a rule.

A valuable aid in posterior urethritis and in some severe cases of anterior urethritis—in cases, further, where, on account of a hypospadias, irrigation is difficult—has been found to be a pill or capsule containing one or two grains of methylene blue and four grains of boracic acid. A rather serious objection to it is the color of the urine, as it may stain the patient's underwear unless great care is exercised by him. In all these manipulations the utmost gentleness is observed and naturally is of the greatest importance, and minute attention to details is also important. The proper performance of irrigation has to be learned, just as the proper method of passing a sound or any other manipulation upon as sensitive an organ as the human urethra has to be learned. In some cases where the acute stage is advanced and the urethra extensively inflamed, if the patient shrinks from the irrigation it is omitted the first day or so, the protargol (beginning with one per cent) alone being used, and the pill of methylene blue and boracic acid given, warning the patient that it will change the color of his urine. Then after his confidence has been gained, irrigation is also employed. The stronger solutions of permanganate have generally proven of too great discomfort in the majority of cases in private practice, and even 1:4000 is not well borne in the posterior urethra in some very few sensitive cases.

The typical course of a case which has come within forty-eight hours after first noting the discharge is about as follows: The first visit is apt to be in the afternoon. The second, if possible, the next morning at eight, the patient holding in his bladder the urine from over night. The discharge at this second visit is slight, and but few gonococci will be found. The next visit is to be at 6 or 8 P.M., the urine having been held at least three hours. The discharge is very slight, numerous pus cells in the field; often, however, no gonococci are found. Next visit the following morning at eight. Some edema about frenum, but no discomfort. Pus cells will be found and perhaps a few isolated pairs of gonococci. The next visit that evening at six or eight; pus cells, but no gonococci; edema of frenum about the same; discharge thin, inclined to be watery, and very slight. The next visit then is made in twenty-four hours; edema almost disappeared; sometimes there is a slight rustiness, due to a tinge of blood, in the very slight watery discharge; sometimes, after long search, one or two groups of intracellular gonococci may be found, and in favorable cases—in fact, in most of the cases of this group—no gonococci are seen again after this. The patient notes that on getting up in the morning there is rather more discharge than at any other time (this, frequently examined, will be found to contain pus, epithelium, and fibrin). Patient comes once each of the next two days, and this finishes the first week. During the second week he comes every other day. He may continue to have a watery discharge, harding amounting to more than moisture and composed largely of epithelium, though pus cells may still be present. This diminishes steadily during the week. The third week he may be seen twice; then he should report again in seven days. There is then generally no mois-
ture; the first glass may contain a faint floating mucous shred composed largely of epithelium. He then is tested by drinking beer freely, either for forty-eight hours or during the following week, and then presents for examination. He is then told to live his ordinary life, to avoid coitus, and advised to report in a month, but to report at once if anything goes wrong. At this last visit he is carefully examined, prostate and seminal vesicles being examined also. This usually closes the attack.

Of the cases observed there were 105; of these, thirty-four had disappeared from treatment too soon to form any conclusion, some having received only one treatment and others three or four. In some instances friends have reported that they were all right and did not need any further treatment.

Of the cases coming for a longer period there were seventy-one. Those coming with a first attack were forty-six in number; sixteen came within forty-eight hours of the beginning; twenty between the third and seventh day; ten came after the disease had lasted between ten days and three weeks. It is natural to suppose that there should be some differences noted in these different classes; the difference in the average is slight if three prolonged cases in those coming between the third and seventh day are thrown out.

Of the sixteen cases, the average time for final disappearance of the gonococcus was fourteen days; average length of treatment, twenty-one days; one case failed. Of the twenty cases three were prolonged, two practically becoming chronic; in the remaining seventeen the average number of days before final disappearance of the gonococci was seventeen; average length of treatment, twenty-six days. Of the ten cases, the average time for the gonococcus was eleven days; average length of treatment eighteen days. These figures are of but little value, as many of the cases would disappear for a few days, thinking they were all right, and return with a return of the discharge; others would omit a day now and then for lack of time to come.

THE MECHANICAL TREATMENT OF TUBERCULOSIS OF THE SPINE AND LATERAL CURVATURE.

PHelps (Post-Graduate, March, 1899) states that among the chief causes of lateral rotary curvature are heredity, paralysis of the groups of muscles, a short leg, intra-uterine causes, bad position in sitting or standing of the rapidly growing child, injuries to muscles at the time of birth, which prevents their development, twist of the pelvis, producing rotation, bad nourishment and bad hygienic surroundings, and rachitis.

In the treatment of Pott's disease, the principles are extension to relieve pressure and fixation to prevent the trauma of motion—extension to the point of comfort, and fixation with a dressing comfortable to be worn and impossible for the parent to remove. By extension and fixation is meant extension and fixation all the time, both day and night, in bed and out of bed. In lateral curvature there can be only harm done with a steel brace, because it cannot be anchored at the pelvis to make proper lateral support; and a narrow pad or bar is bound to excoriate from pressure, and the patient will remove it.

The same objection holds good in Pott's disease. The anteroposterior lever of Taylor cannot be worn constantly, and then in
cases of the slightest lateral deviation of the spine, it aggravates the deformity by twisting the spine upon its axis, hence the old statement that "the deformity usually increases at first when the brace is applied."

Apply a well-fitting plaster-of-Paris or aluminum corset, and the deformity will not increase. A steel brace to protect Pott's disease is like the first locomotive, that required a man to open and shut the valves at the right time, or things would not go. The plaster-of-Paris or aluminum corset is like the perfected mogul engine that runs without care after the throttle is open.

The application of a steel brace of any make in Pott's disease of the spine, where there is the least lateral deviation, is a practice to be condemned, because such cases invariably increase in deformity, on account of the mechanical conditions. Destruction of bone will certainly increase, whereas if suspension is applied and a properly fitting corset adjusted, no pressure is made at the point of disease, and the rotation will not increase.

In making a plaster-of-Paris corset for Pott's disease or lateral curvature, place under the gauze shirt a "dinner pad," a folded towel, to make room for distention of the stomach. The "cross-bar crinoline" is objectionable for the bandage material, because it carries too much water and interferes, therefore, with the "setting" of the plaster. The best material is the cheapest of crinoline, which contains little or no sizing. It comes in twelve-yard lengths. Tear this in two, making a piece six yards long. This is to be torn up in strips five inches wide. This furnishes the best foundation for the plaster bandage. Only just so much plaster should be rubbed into the bandage as will be retained by the meshes of the crinoline; the plaster should not lie loosely on the bandage. The success of a corset depends very largely upon the first bandage applied. The patient is suspended slightly by means of the chin- and shoulder-straps. The first two or three turns of the bandage are applied snugly around the lower part of the abdomen at the middle and down on the pelvis. Only about three or four bandages will be required for a patient five years old, commencing at the bottom of the corset with each subsequent bandage. Be sure to rub the layers of bandage well together with the hand, so as to get rid of the air; it is not a heavy but a compact bandage that is required. This is a very simple process, but the success of the plaster-of-Paris corsets depends upon the amount of cerebral matter mixed with them.

It is desired to utilize the principle of anteroposterior pressure when necessary, but not in lateral curvature; it is also desired to hold the patient in the suspended position. Press the corset in over the crest of the ilium to prevent it from slipping. These are the main ideas to be followed out in the application of the plaster-of-Paris corset. Now that the plaster is just setting, the body is seized with both hands on either side, and counter-pressure is made between the vertebrae, placing the weight of the body upon the transverse and articular processes. But it would not do to leave the bandage this way, for it would soon cause excoriation. Remove the "dinner pad," and then press the corset a little anteroposteriorly over the abdomen. In this way the corset is slightly "sprung" away from the anterior superior spinous processes, and excoriation is thus prevented. Of course the corset will need be trimmed off a little at the top and bottom. A sharp knife is the best instrument for cutting away soft plaster-of-Paris corsets. Another important practical point in applying plaster-of-Paris bandages to fractured limbs is that if a plaster bandage while still soft is cut nearly through, and then an ordinary bandage applied, much less difficulty will be found in removing the plaster bandage. The plaster-of-Paris corset is applied over a long stockinet shirt. The lower portion of the shirt can be turned up over the corset, thus giving it a nice finish.

In regard to the treatment of lateral curvature of the spine, the principles involved are entirely different from those of Pott's. In Pott's disease a permanent corset is applied for the purpose of fixation and extension. In lateral curvature the support is applied for the purpose of fixation and extension during the time the individual is in an erect position; it is removed at night, and gymnastics with proper breathing exercises should be done while the patient has on his support, because greater benefits are derived from this method than from removing the support during gymnastics. In lateral curvature of the spine the principle of treatment is extension and fixation to relieve pressure at the point of curve, which prevents the further absorption of bone. Gymnastics, muscular and respiratory, are used for the purpose of strengthening the spinal muscles, increasing the capacity of the thorax, and aiding in forming compen-
satory curves. Nearly all cases of lateral curvature of the spine in which the deviation from the median line is more than one-half of the diameter of the body of the vertebrae should be braced, else absorption of the vertebrae from pressure is bound to go on. Phelps states that he has seen hundreds of these cases treated by the best gymnasts of the Ling method and other methods of gymnastics from the hands of the best orthopedists, and they have almost invariably given a history of increasing deformity. It is for this reason that he urges the profession to brace the class of cases designated with a proper fitting plaster-of-Paris corset or an aluminum corset. The aluminum corset is an ideal spinal support. The wood corset, the author believes, would fill the requirements in all cases, but he found that every form of wood corset would change its shape, as do also the sole-leather, rawhide, felt, celluloid, and paper corsets. The patient will invariably shorten during the warm weather with these dressings, but with a plaster-of-Paris or aluminum corset this shortening will not be observed, and the test of any support is the question of how much taller it makes a patient. An aluminum corset has this to recommend it: it will not change its shape, it is almost indestructible, and when well shelledack the perspiration will not affect it. It is light and perforated, which makes it a very cool corset in the summer-time, being made entirely of metal. Patients with Pott's disease of the spine wearing the aluminum corset are enabled to go in bathing at the seaside during the summer months, which is a very great advantage.

In regard to the operative procedure in lateral curvature of the spine, where very strong bands of muscles are found stretched across the curves, such patients are to be etherized and these muscles divided. Frequently two to six inches is gained by an operation of this kind.

**Sarcoma of the Brain Successfully Removed.**

Carle (Revue de Chirurgie, Feb. 10, 1899) removed a sarcoma from the left frontal lobe of a patient who suffered from motor aphasia paralysis of the hyperglossal nerve and of the lower branches of the facial, together with marked diminution in the intelligence. Two and a half years after operation the patient was perfectly well, with unchanged intellectuality. The only remaining sign of trouble was slowness of speech.

**Non-malignant Ulcerations of the Esophagus, with Especial Reference to Simple Perforating Esophageal Ulcer.**

Russell (Scottish Medical and Surgical Journal, April, 1899), after calling attention to the slight notice accorded simple ulceration of the esophagus in English and American textbooks, contributes an admirable study of the affection.

Perforating ulcer of the esophagus presents practically the same anatomical features as ulcer of the stomach. If it be small in size, it retains the classical appearance of sharply-cut, shelving edges; if large, the ulcer tends to become annular, surrounding the tube, or sometimes irregular. It may or may not perforate all the coats of the esophageal wall. The condition of the peri-esophageal tissue seems to depend on the length of duration of the ulcer. In some cases, such as Flower's, the ulcer perforated the aorta before any new fibrous tissue had formed between the tubes. In other cases we read of dense adhesions between the esophagus and neighboring organs.

If cicatrization has taken place, the ulcer is represented by a puckered white radiating cicatriz similar in appearance to healed ulcer of the stomach.

Esophageal ulcer occasionally occurs concomitantly with gastric or duodenal ulcer. In such cases the diagnosis is still more difficult.

The records do not throw much light on the etiology of simple perforating ulcer. Several facts, however, may be gathered from them. The condition differs from gastric ulcer in the following points: (1) Males are much more frequently attacked than females; in twenty-three cases seventeen were males, six females. (2) It is a disease of middle and advanced life. The patients' ages range chiefly from forty to sixty-seven years. In only five cases were the patients under thirty-five. (3) Anemic conditions are not mentioned as concomitants of the disease.

Syphilis and habits of intemperance have been noted in several of the cases, but there is no evidence that either of these is an important etiological factor. In some of the cases the ulcer appears to have caused death in persons who had previously presented no pathological symptom.

The pathology of the condition rests in the same position as that of ulcer of the stomach.

Quincke named his cases Ulcus esophagi ex digestione, and believed them to be due to the
action of regurgitated gastric juice. Similarly another writer entitled his paper "Pep-
tic Ulceration of the Esophagus." Debove and Berrez, however, believe that this view
of the causation both of gastric and esophageal ulcers is untenable, and hold that the
cause is still undiscovered.

It is very apparent from the cases recorded that there is no symptom absolutely pathog-
nomonic of esophageal ulcer. Unfortunately, too, in many instances the condition gives
rise to no symptoms, or to symptoms so slight as to be entirely overlooked, until the condi-
tion of the patient suddenly passes beyond the power of treatment. Still, in many in-
stances it is quite evident that the patients' lives might have been saved had the cases
been diagnosed and proper treatment under-
taken.

The first symptoms usually appear to be pain on or after taking food, and vomiting of
the matter ingested. The pain in most cases is situated either between the shoulders, be-
hind the sternum, or in the back at the level of the lower dorsal and upper lumbar verte-
bræ. Pain is also occasionally present in the epigastrium. The pain usually begins as the
food is being swallowed; sometimes, how-
ever, it is not complained of as occurring so early.

Later on in the disease the course of events is that the patient begins to have diffi-
culty in ingesting food, the food being at once regurgitated from the esophagus as
soon as the act of deglutition has taken place. At the same time hematemesis, more
or less severe, is a common symptom. Berrez says that the hemorrhage is never so severe
as it may be in gastric ulcer, from the fact that the esophageal vessels are so much
smaller than those which run on the surface of the stomach. In the cases recorded where
hemorrhage has been sudden and fatal, the cause was always perforation into the aorta
or one of its branches.

In spite of the apparent obstruction in the esophagus, usually at this stage no actual
constriction can be discovered on passing a sound.

The condition may then either begin to progress towards cure, or may cause the
death of the patient, the fatal termination being due either to perforation of some im-
portant structure or to the debility caused by the hemorrhage and inability to swallow or
retain food. Perforation, if it occurs, is most commonly into the air-passages. Perforation
of the pericardium, pleura, or one of the great vessels has been reported.

If the ulcer goes on to cicatization, a se-
vere stricture may be the result, and may
cause death of the patient from slow starva-
tion. Thus the patient in the early stages of
the disease may suffer from apparent stric-
ture, and later require treatment for actual
striction, of the esophagus. The cases of De-
bove are good illustrations of the latter stage of
the disease. In each of these cases the
patient was evidently not far from a fatal
termination when treatment was commenced.

Cancer of the esophagus and ulcer of the
stomach are the diseases with which simple
esophageal ulcer has been most frequently
confounded, and in many of the cases re-
corded it would have been very difficult to
make any other diagnosis.

Hemorrhage from the esophagus may be
due to varicose veins. This condition is
chiefly seen in cases of cirrhosis of the liver.
The possibility of diagnosis between simple
perforating ulcer and the other forms of non-
malignant ulceration would depend almost
entirely upon the presence or absence of a
definite history or diathesis, which might lead
one to suspect on the one hand the effects
of a foreign body or irritant poison in the
esophagus, or, on the other, ulceration of a
 tubercular or syphilitic nature.

In sounding the esophagus one must bear
in mind the possibility of being misled as to
the presence or absence of stricture, by the
sound passing into a diverticulum. Perfora-
tion of the air-passages would be indicated
by the patient immediately beginning to
cough after swallowing food, and later by
the development of a septic condition in the
lungs.

Treatment must be carried out on general
principles. The ulcerated area must be saved
from irritation as much as possible by the
giving of bland foods, aided by rectal alimen-
tation, and if the condition be obstinate, by
the formation of a gastric fistula. If there
be any suspicion of syphilis, antisYPHILITIC
remedies should be tried in the first in-
stance.

If a stricture has formed, dilatation should
be performed, provided the ulcer appears
to be healed, but if hemorrhage is still going
on, and there is much pain, it would appear
to be wiser to give the esophagus rest for a
time before undertaking dilatation. In some
cases surgical intervention by way of the
posterior mediastinum might be of great
value. After perforation of the air-passages there might still be some hope for the patient in the formation of a gastric fistula, but perforation of the pleura, pericardium, or aorta must almost of necessity prove fatal.

A CONVENIENT TECHNIQUE FOR THE DELIVERY OF THE AFTERCOMING HEAD WHERE GROSS DISPROPORTION EXISTS.

Stahl (American Journal of Obstetrics, April, 1899) reports a case of labor delayed by hydrocephalus, in which he decapitated, turned the head, perforated it by means of blunt scissors, evacuated the liquid contents, and delivered without difficulty and without the slightest injury to the mother.

Given one hundred cases presenting the usual malconditions as to pelvocephalic disproportion, the advantages will be found to lie with the perforation and extraction of the advancing head rather than with the perforation and extraction of the aftercoming head, for, however masterful the obstetrician, the following conditions will obtain:

1. The cephalic parts in the aftercoming head are more difficult of access.

2. The avenue of approach, because of its embarrassment, is more awkward for operation than when clear of obstacles like the neck and trunk.

3. The assistance required is greater and more complicated.

4. The length of time of operation is longer.

5. The evacuation and breaking down of the brain is accomplished with less facility.

6. Extraction of the aftercoming perforated head manually or with instruments requires greater and more delicate efforts.

7. The dangers from slipping of instruments, ruptures, lacerations, and pressure inflammations are greater.

8. With the aftercoming head choice of vantage puncture is limited; the head cannot be turned or adapted as emergency or advantage may suggest. In the advancing head, and more especially when decapitated, the head can be turned, without difficulty or danger, into any form of presentation desired, so that any point, as a fontanel or suture, may be chosen for attack.

9. The extraction of the aftercoming head presents more difficulty for the general practitioner, as well as for the specialist, than does the extraction of the advancing head.

10. As Winternitz declared, decapitation, turning, exacerbation, and extraction (his case with craniotomy) requires, comparatively speaking, little time.

A short excerpt of Stahl's case is as follows: Parturient, thirty-two years old, well and healthy appearing; had four labors within four years, all with assistance. First labor: Forceps, difficult, at pelvic outlet; neonatus died a few hours postpartum. Second labor: induction of labor at thirty-third week; spontaneous delivery of 2840 gramme child; died one day after. Third labor: prolapse of cord and foot; reposition; spontaneous delivery of premature child; lived. Fourth labor: occipito-posterior presentation; premature; forceps at pelvic outlet; lived. Fifth labor, present case: A generally contracted pelvis with a conjugata diagonalis of 9.9 centimeters; conjugata vera, 7.5 to 7.7 centimeters; position first breech; membranes ruptured at 12 midnight; breech soon appeared; extraction difficult; right arm extracted with fracture; head high above superior strait; notwithstanding strong tractive attempts, did not descend; attempts made to perforate; no room in vagina for perforator; while attempting to perforate a profuse hemorrhage occurred, due to premature separation of placenta; pulse became small, face blanched, the patient threatened to collapse; decapitation, turning, perforation through vertex; hemorrhage still continued; applied cranioclast, soon delivered head; prematurely separated placenta immediately followed head; uterus contracted firmly, hemorrhage ceasing; one hour and a half postpartum, after various stimulation, the patient could safely be committed to the nurse's care; pueroerium normal; neonatus 3500 grammes.

Kilian in 1849, Fehling in 1889, both warned against exerting such traction upon the trunk as to separate it from the head. Under normal conditions and under moderate disproportion this suggestion is a very good one. Here, if the head be not spontaneously delivered, manual methods alone usually develop it. But where gross disproportion exists this objection need not stand, as decapitation with perforation, etc., may be performed as readily—more so, no doubt—as perforation, etc., of the aftercoming head with trunk still attached.

Will this method of decapitation and extraction prove as successful when dealing with the normal head as with the hydrocephalic? The author thinks so, and that it should yield as favorable results. If it were necessary the turned, perforated, collapsed,
thus advancing head could readily be disarticulated and extracted with the light, small Meigs or Mesnard forceps, and with less embarrassment than when crushed and spiculated with the heavy machinery of the cephalotribe.

REPORT OF NINE ABDOMINAL SECTIONS FOR EXTRA-UTERINE PREGNANCY.

Hirst (American Journal of Obstetrics, April, 1899) last year reported twenty-one operations for extra-uterine pregnancy. He has had since then nine more, making a total experience of thirty operations. These last cases teach no new lessons. There were, however, several interesting cases among the number. Two were apparently only fourteen days advanced, judging from the size of the tumor and the clinical history. One of the specimens showed a swelling of the tube not over half an inch in its longest diameter, and yet the amount of blood in the abdominal cavity in this case was unusually large. In another case, in which the woman had already given birth to twins twice, there was every evidence of a coincident intra-uterine pregnancy, which had not yet been interrupted by the operation. The patient had not menstruated since the operation, and the uterus was steadily enlarging, but it was too early to elicit positive signs of pregnancy. One of the cases had an extraordinary history, and was operated on for a pus tube on one side. The other tube and ovary, carefully inspected during the operation, were dropped back unmolested, as they appeared perfectly healthy. Four and a half weeks later there were symptoms which under any other circumstances would have been recognized as those of tubal pregnancy, but such an idea did not occur to the author. After three or four such seizures in the next five or six days a mass appeared in the pelvis involving what had been the healthy tube and ovary. The supposition was that an infection had traveled up from the uterine cavity; the abdomen was reopened, and a ruptured extra-uterine pregnancy found. The woman must have been impregnated immediately before entering the hospital, and in the first operation a tube with an impregnated ovule in it had been handled, naturally without suspecting it. Of the thirty patients three died, one of cirrhosis of the liver and gastritis, a chronic drunkard, in the Philadelphia Hospital; the other two of acute anemia—they had practically bled to death before the operation was attempted.

HYSTERECTOMY FOR PUEPERAL SEPSIS.

Hirst (American Journal of Obstetrics, April, 1899) has averaged for the last few years at least four hysterectomies a year for puerperal sepsis. During the past winter he has had three such operations, and in addition has had a number of other operations for puerperal sepsis. Recently he had a case in which an incision was made over the groin and another in the loin, washing out a quart of pus by through-and-through drainage.

There is no such thing as specific operation for puerperal sepsis. One is occasionally obliged to remove a necrotic or gangrenous uterus, just as he would be obliged to remove a foot of gangrenous intestine. We might as well expect a patient to get well with such a uterus left in the body as to expect her to recover without removing a gangrenous portion of gut. These necrotic uteri have the consistence of cheese. Nothing holds in them. They are perforated easily by the finger-tip. The whole uterus is one vast nest of streptococci, and it would be just as sure to kill a woman, left in her body, as an enormous injection of a virulent culture.

The author has had twelve hysterectomies for puerperal sepsis with one death in the last three years, which is a good illustration of what can be done by operation. One of the cases was brought into the hospital with a temperature of 104°, pulse 140. She was intensely emaciated and had that grayish color of the skin which we see in advanced cases of septicemia. There was a large mass filling up the whole of the pelvis. When the abdomen was opened it was found that the tubes and ovaries were involved, the broad ligament being an inch thicker than normal, and the uterus so soft that it could be pinched through between the thumb and forefinger. Everything was taken out—the tubes, ovaries, and as much of the broad ligament as could be gotten away. The woman made a tedious but good recovery, and is now perfectly well. These cases, of course, need the freest kind of drainage with both gauze and tube.

Another case was one of criminal abortion. The patient came into the Howard Hospital with a rapid pulse and hectic fever. She was operated upon, and the uterus was found perforated in one place. The whole pelvis was full of stinking pus. All the pelvic organs were taken out. She made a good recovery.

In another case the patient had a temperature of 104°, the pulse was 140, and the woman was almost comatose. She seemed to
recognize nobody and only replied to questions asked in a very sharp tone of voice. She was as far gone as any patient in sepsis whom the author has ever seen recover. The abdomen was opened and the uterus and other pelvic organs taken out. The wound was drained with both gauze and tube. The broad ligaments were so thick that no mass ligature could be applied. The bases of the broad ligaments were left open. The whole pelvic cavity was packed with gauze and a large glass tube was placed in Douglas’s pouch. This was replaced in forty-eight hours by a rubber tube, through which the pelvic cavity was irrigated daily with sterile water. Within twenty-four hours of the operation the woman’s temperature was below 100°, consciousness returned, and her pulse was under 110, and from that moment she had no bad symptoms. A sinus remained for some months, but gradually closed, and she is now perfectly well.

These are types of cases which need hysterectomy, and without that operation they are absolutely doomed. The author thinks this proposition is unassailable.

The woman whose uterus was exhibited, the author stated, was no worse than many he has seen get well. It is the only case that he lost from an operation for puerperal sepsis in the last three years. The uterus had, when it was taken out, the characteristics which have been described. Although the seat of infection was removed and the operation quickly done, the patient died. The result is no argument against the procedure. It is impossible to be successful invariably in such desperate cases. That woman could not have recovered without the operation; it gave her the only chance she had.

GANGRENE FOLLOWING THE APPLICATION OF ORTHOFORM SALVE.

Miodowski (Münchener Medizinische Wochenschrift, No. 12, 1899) reports a case of sloughing following the application of five-per-cent orthoform salve. A woman, sixty-eight years old, suffering from an old varicose ulcer of the leg, having been treated by a zinc preparation, complained of violent pain radiating to the knee, and so severe as to interfere with sleep. A five-per-cent orthoform salve was applied to the ulcer, with the result of almost immediately relieving the pain. The patient was able to sleep comfortably. Upon inspecting the wound about a week later, a large slough was found in the position of the ulcer; the latter had extended. In this case (as far as the report of it goes) it is not fair to conclude that the gangrene was due to the orthoform salve. It is noteworthy, however, that the application relieved the severe pain of the inflamed ulcer.

AMYLOFORM AND IODOFORMOGEN AS SUBSTITUTES FOR IODOFORM.

Heddaeus (Münchener Medizinische Wochenschrift, No. 12, 1899) was asked by Czerny to test these two drugs. The amyloform is a chemical combination of formaldehyde with starch. It is stated by Bongartz to be free from irritating qualities, non-toxic, strongly disinfectant, and with a marked effect in diminishing secretion. This opinion is corroborated by Heddaeus. The drug is not soluble, hence can be used only as a powder. It can be either dusted on the wound or insufflated. A number of illustrative cases are reported, showing the excellent results of the drug. In many tuberculous affections the rapid disinfecting power of the amyloform was clearly proven. In no instance was there any irritant effect, such as ezema, observed. When it was applied to large granulating surfaces there was often felt at first slight burning. No intoxication symptoms were ever developed. It is commended by the author as a thoroughly admirable, efficient, antiseptic dusting powder, which in many cases can substitute iodoform, and which, because of its absolute freedom from irritating properties, is to be preferred to many of the newer antiseptics. Its most important action is the cleansing power it exerts on suppurating wounds, and hence its principal application will be found in the treatment of superficial supplicative affections.

Iodoformogen, a preparation of iodoform and albumin, is a clear yellow powder, insoluble in water, and almost without odor. It contains ten per cent of iodoform, and since it is prone to decompose, forming iodine, it should be kept in dark bottles. Iodoformogen was used in a large number of cases, some of which are reported. It was found to be decidedly antiseptic, markedly lessening the secretion, favoring the formation of granulations, and exerting a specific influence on tuberculous processes. It is ranked as next to iodoform in this respect. The author states it is doubtful whether it will entirely displace iodoform. It is much less toxic than iodoform, and is devoid of the unpleasant odor of this drug.
THE RELATIONS OF A MOVABLE KIDNEY AND APPENDICITIS.

EDEBOHL (Medical Record, March 11, 1899) proves by his clinical and operative work that chronic appendicitis is present in from eighty to ninety per cent of women with symptom-producing movable right kidney. This frequency constitutes chronic appendicitis one of the chief, if not the chief, symptom of movable kidney.

Chronic appendicitis by reason of its frequency, the protracted suffering and serious impairment of health which it entails, and the dangerous possibilities of implanted acute attacks of appendicitis, may be considered the most important complication of movable right kidney.

Twenty per cent of all women have movable kidney or kidneys; four per cent have appendicitis; and while three and one-half per cent have both symptom-producing movable kidney and appendicitis, only one-half per cent have appendicitis and well anchored kidneys. The startling nature and importance of the conclusions to be drawn from these statistics do not invalidate the latter.

Satisfactory investigation of the relations of movable kidney and appendicitis became possible only after the discovery and elaboration of the writer’s method of palpation of the vermiiform appendix. It remains impossible to those not practically familiar with the method.

Chronic appendicitis may be the only symptom of movable right kidney.

Some of the symptoms commonly ascribed to movable kidney are often in reality due to the concomitant appendicitis. The relations existing between movable right kidney and chronic appendicitis are those of cause and effect. A movable left kidney never produces appendicitis.

Movable right kidney probably produces chronic appendicitis by indirect pressure upon the superior mesenteric vein, the return circulation of the appendix being hampered by compression of the vein between the head of the pancreas and the spinal column.

Chronic appendicitis associated with movable kidney shows no tendency to resolution or spontaneous cure, with restoration of a normal appendix, while the right kidney remains movable. The only cure possible under these conditions is by slow progress to appendicitis obliterans.

In twelve of the writer’s cases of coexisting movable right kidney and appendicitis, the appendicitis apparently ended in resolution and remained permanently cured after right or bilateral nephropexy, without any attention to the appendix.

Recovery from appendicitis after right nephropexy may only be expected in cases in which the associated chronic appendicitis is of comparatively recent origin.

In a minority of cases only of associated movable right kidney and chronic appendicitis will either nephropexy alone or appendectomy alone meet all the indications. The majority of patients require both operations to restore them to full health. Both operations, right nephropexy and appendectomy, may be simultaneously performed through one lumbar incision extending along the outer margin of the erector spinae muscle from the twelfth rib to the crest of the ilium.

Correspondence.

LONDON LETTER.
BY RAYMOND CRAWFURD, M.A., M.D. OXON., M.R.C.P. LOND.

Since my last letter the election of President of the College of Physicians has come and gone. Somewhat to the surprise, but none the less to the satisfaction of the faculty, Dr. Church, senior physician of St. Bartholomew’s Hospital, has been elected; his most serious opponent was Sir William Broadbent, but the College has probably done wisely in selecting the candidate who has the greater amount of leisure available for its affairs.

It is gratifying news to learn from official returns that the “conscientious objector” to vaccination has not after all proved to be the danger that was anticipated. As a matter of fact it is now beyond question that with house to house visitation and the general employment of glycerinated calf-lymph, vaccination is decidedly on the increase. Under these circumstances the Antivaccination League must in the nature of things redouble, and have indeed already redoubled, their efforts to propagate their vain doctrine. Meantime the Jenner Society has urged upon the President of the Local Government Board the desirability of giving effect to two very practical proposals: first, that the certificate of successful primary vaccination should in all cases record “the number of separate scarified areas, punctures, or groups of punctures made, and the number of separate normal vaccine vesicles which have been produced,” and should be registered and kept as
a permanent record; secondly, that the certificate should bear on its face some statement of what in the opinion of the Local Government Board constitutes "efficient," as distinguished from "successful," vaccination, so that parents or guardians who refuse to have their children vaccinated according to the "standard so prescribed may at least be informed of the responsibility they incur in so doing.

At the Clinical Society on April 1 modern surgery was very much en fête. The President related a case of aneurism of the abdominal aorta successfully treated by the introduction of silver wire. Although this operation has been several times attempted, the number of successful cases is, I believe, extremely small. In this case the attempt seemed to be justified by the position of the aneurism at the commencement of the abdominal aorta, which seemed to preclude other less hazardous methods of interference. The sac was first punctured by a trocar and cannula, and not much blood issued when the trocar was withdrawn; five feet of silver wire was then introduced through the cannula. The puncture was obliterated by means of a silk ligature. It is now a year since the operation, and the large aneurismatic sac has shrunk into a small hard knot in the middle line. All the diagnostic signs of aneurism have disappeared, and the patient's symptoms are completely relieved.

At the same meeting Rutherford Morison, of Newcastle, showed a remarkable series of cases illustrating the result of operations for pyloric obstruction. A case of pyloroplasty shown was one of nineteen cases in which Morison had operated successfully for relief of simple stricture of the pylorus. The incision was made 1 ½ inches from the pylorus, and a guide passed through it; then an incision was made through all the coats, and so sutured as to make the line of union transverse to the incision. The five remaining cases were patients for whom pylorectomy had been performed for malignant disease. Looking at the patients it was difficult to believe that each was without some portion of the stomach, up to as much as one-half of the organ. The dyspeptic might well ask why Nature has cursed him with this malevolent and useless organ. There was no room to doubt the character of the disease with which the operator had had to deal, as both the portions removed and microscopic sections of them were laid before the audience. In these cases Morison had obtained end-to-end anastomosis of the stomach and duodenum instead of closing the cut ends of both organs and making an overlapping anastomosis. The uniform and almost invariable success of the operation in the cases in which Morison had performed it more than compensated for the fact that the operation was in no sense a new one.

A year or two ago Dr. Washbourn recorded in the British Medical Journal some interesting and satisfactory experiments with an antipneumococcic serum he had prepared, and recounted also two cases of pneumonia in which the serum appeared to have been employed with marked benefit. Since this Dr. Pane, of Naples, has prepared an antipneumococcic serum in large quantities, and Washbourn has recently experimented with this. Pane's sera are of two strengths, and Washbourn has shown that the stronger of these two standardized sera has practically the same protective influence against cultures of the pneumococcus as his own serum had. These results justify us in looking for an extended therapeutic application of antipneumococcic sera in various affections of pneumococcal origin.

An interesting communication was read by Dr. Maguire to the Medical Society of London on "Death from Functional Nervous Disease." The cases he seeks to include in this category are those in which the only system at fault appears to be the highest nervous centers, and that without a trace of organic disease. Thus senile decay falls outside the category, as here almost without exception one can point to deterioration of some one or other somatic function, usually that of the heart. In the cases recorded by Maguire death was in each case preceded by a period of unconsciousness of greater or less length, and the most careful examination failed to exhibit disease of any organ, or the existence of any toxemia. In some of the cases there was positive evidence of severe mental strain preceding the symptoms. Dr. Maguire attributed death in these cases to exhaustion of gray matter. The likelihood of this explanation is confirmed by the analogy of the protracted periods of unconsciousness which not infrequently follow the epileptiform seizures in general paralysis of the insane, where the higher nervous centers fail from organic disease. If Dr. Maguire's speculations be correct, it behooves every physician to foster in his patient the spirit of hopefulness. Thus the sense of impending death is of little importance in the young and
acutely ill, so long as the recuperative powers are active, but of grave ill omen in the old and in those enfeebled by protracted disease. At the Royal Academy of Medicine in Ireland a paper was read dealing with the effects of minute quantities of sodium chloride on the secretion of urine. Solutions of sodium chloride of less than one-per-cent strength were injected into the external saphenous vein of dogs in quantities varying from thirty to fifty cubic centimeters. Urine was collected from both ureters by means of canulae both before and after the injection of the salt solutions. The results showed: (1) A marked increase in the amount of urine secreted, which reached its maximum in the second hour after the injection, but had not wholly subsided even at the end of four hours. This increase far exceeded the amount of fluid injected. After making allowance for this quantity, the average of ten experiments showed an increased output of over 300 per cent. (2) Both the total nitrogen and the urea also suffered an increase, though the urine secreted was more dilute. The increased output of solids reached its maximum in the hour immediately following the injection. These effects were not due to dilution of the blood nor to a hydremic plethora caused by the injection, nor could they be ascribed to the necessity of getting rid of the sodium chloride, as in many cases the actual output of chlorides was diminished.

The medical officers of health by the mouth of Dr. Hill have brought a grave indictment against the provision merchants of the metropolis. Most of the articles of food in daily consumption appear to be contaminated to an alarming degree with antiseptics. Milk, butter, and cream appear to be habitually deluged with boric and salicylic acids; so also sausages, hams, tongues, and the various tinned meats. On the whole we prefer to have our milk and butter free from decomposition even at the expense of a few grains of boric acid, but to find that some samples of butter contain as much as eighty-four grains to the pound gives one pause. There can be no doubt that the habitual ingestion of boric acid, particularly in infants, provokes various catarrhal ailments, while salicylic acid must be admitted to be an actively dangerous drug. The medical officers of health call on us to rise against this wholesale system of adulteration, as other countries have done. Let us not, however, follow the example of France, where adulteration is strictly prohibited except in the case of exports, which are adul-

ated to a degree unknown even in this country. In the course of the discussion Mr. Carsal, a public analyst, stated that he always took up the position in a court of law that "if a substance were present in quantity sufficient to exert an antiseptic action it must de facto inhibit digestion, and therefore it must if of any use be harmful." As the proponent of this contentious thesis Mr. Carsal is to be congratulated on the fact that medical men—and in particular specialists in diseases of the stomach—are exempted from serving on juries. The reasonable position seems to be not to forbid the use of preservatives, but to insist on a clear declaration of the nature and amount of the preservative employed.

Experiments in the treatment of Malta fever at Netley Hospital with the serum antitoxin have so far given satisfactory results. The treatment must needs be carried on at present in the face of considerable difficulties, as it cannot be said that as yet we are clear as to what Malta fever is, or rather what is not Malta fever. One finds all the various fevers of the Mediterranean seaboard roughly drafted into this category, but research has shown that these include several distinct varieties; even cases of typhoid fever and malaria are now and again dubbed Malta fever. Apparently we are clear as to the identity of the organism, and with that ascertained beyond dispute we should be well on the way to elaborating an effectual antitoxin. Every physician will admit that the therapeutic armory contains no drug of any peculiar benefit in the treatment of a case of Malta fever.

Liverpool has shown the way to London in the establishment of a School of Tropical Medicine. London it is true is not far behind, thanks to the energy of the Colonial Secretary. Last week the inaugural ceremony in connection with the Liverpool school was held amid great enthusiasm. The clinic of tropical diseases at the Royal Southern Hospital is even superior to that of the Seamen's Society in London, and with the admirable Thompson-Yates laboratories for research, and with Major Ross at the head of affairs, the school starts its existence under the happiest auspices.

Special attention is due to the report in the last number of Brain of the discussion at the Neurological Society on the localization of intracranial tumors. The discussion served to show the many doubts and difficulties in the matter of accurate localization,
more particularly in the silent areas of the brain. It was abundantly evidenced that the site of the headache in cases of frontal and cerebellar tumors was subject to the widest variation, and could not be relied upon in localizing, but that in the presence of other signs of a cerebellar tumor, headache referred to one or other side of the frontal region usually indicated a tumor on the opposite side of the cerebellum. Optic neuritis tends to be rapidly developed, and of highest intensity in tumors of the posterior fossa; if the neuritis be unilateral, or more intense on one side than on the other, the side of greater intensity is usually that of the lesions.

**PARIS LETTER.**

---

---

A recent operation performed by Dr. Doleris, accoucheur-gynecologist of the Paris hospitals, and accoucheur of the Boucicault Hospital, tends to show that appendicitis may exist without causing any very serious symptoms. A patient, aged forty, was operated upon, and a fibromatous uterus, containing a small portion showing signs of mortification, was removed. The second day after the operation slight indications of peritonitis became apparent, and on the sixth day the patient died. On examination the appendix was found to be perforated, showing a fistula in a very much thickened wall, and a certain amount of thick pus was discovered behind the caecum. On examining the written report of the case it was seen that the patient said she had suffered from severe colic five months before. This case of appendicitis had developed after the operation, without giving rise to any very accurate symptoms, with the exception of a slight degree of tympanites in the lower abdominal region. The operation had been performed *per vaginam*, and in the post-mortem examination no signs of pus or any abnormal conditions were to be found in the vaginal incision.

Dr. Grillot, assistant of Dr. Letulle, chief physician of the Boucicault Hospital, presented recently to the Society of Anatomy, at a meeting held on April 28, the report of a case which died ten minutes after having been received at the hospital, death being due to a ruptured varicose vein of the external malleolar region of the left leg. Dr. Letulle, who is with Cornil, the most noted pathologist in France, examined the case histologically and found union of the skin and of the varicose vein on a level with the ulceration. This observation shows that though infrequent, hemorrhage from such causes may result fatally.

A question of some importance is whether salicylate of sodium has a preventive action on the occurrence of pericarditis in an attack of acute rheumatism. Dr. Delarade, professor at the Faculty of Medicine of Lille, stated recently in an article on this subject that he thought it the best means of preventing such manifestations. A certain number of rules should, however, be followed out. The first is to prescribe this drug in large doses from the very beginning of the illness. In the adult six to eight grammes should be given daily at first; for the child, fifty centigrammes to a gramme under one year, two grammes from two to five, three grammes towards six years, three to four grammes between six and ten, four to five above that age. Such doses should be given in fractional amounts every three to four hours, as this salt is readily eliminated—for an adult, say a gramme every three or four hours. A third rule is to continue the salicylate at half the above doses for about ten days following the disappearance of the articular pains. This precept comprises all the preventive treatment of rheumatic pericarditis, as this affection does not show itself at the beginning of the attack but later on, and sometimes when the pain has quite disappeared. The best formula according to the author is the following:

Salicylate of sodium, 6 grammes;
Cognac, 10 grammes;
Syrop, 40 grammes;
Water, q. s. ad 150 grammes.

To be taken in large spoonful doses in twenty-four hours.

Recently quite a fright was produced in Paris by a report having been spread that an epidemic of bubonic plague had broken out in a large establishment of dry goods, well known to our readers under the name of the Bon Marché. It seems an anonymous letter had been sent to the *préfet de police*, in which it was stated that five employees of the Bon Marché, whose duty it was to examine oriental carpets, had died from this disease. This news was quite false, and the condition of health amongst the Bon Marché employees has been excellent. It is hard to say whether jealousy was the cause of this alarm; however, one can readily understand that such a report would be apt to injure the sales for at least three or four days.
Dr. E. Perrier, of Paris, has indicated recently a new treatment for the cephalalgia of adolescents:

1. When the pain comes on give from one to three of the following capsules every half-hour: Hypnal, 0.20 to 0.40 centigramme.
2. Every morning a glycerophosphate preparation.

3. Before each meal give in a small glass of malt extract eight to twelve drops of the following mixture:

   Tincture of nux vomica, 2 grammes;
   Tincture of badian,
   Tincture of gentian, 1 dram 0.50 grammes.

4. The food taken should be rich in phosphates: phosphated milk, lentils, beans, good bread, eggs, brains, fish, meats, etc.

5. Stop all mental work and send the child to some elevated country, eight hundred meters above the sea level.

Dr. Ch. Leredde, chief of the laboratory at the St. Louis Hospital, has recently published an article on the treatment of eczema by nitrate of silver. This method has already been used by Dr. Besnier, of the St. Louis Hospital, in the treatment of old circumscribed lichenoid forms of eczema. The author has sought to apply this treatment to extended varieties of eczema, especially when eczema of the hands is present. The mode of application depends somewhat on the stage of the eczema. One point is to use the various methods indicated in the internal treatment, such as cathartics, milk diet, alkalines. Another is to let acute forms which are progressing arrive at their final stage, so long as the cutaneous eczema is on the increase. All sources of irritation should be suppressed as much as possible. Once the eczema is fully come out a thin sheet of rubber should be applied on the skin previously sterilized by compresses of boiled water. Four times a day the rubber is taken off and washed with boric acid water. The skin is washed with boiled water. In this manner all infection is obviated, and in case there is the slightest trace of suppuration, the rubber should be removed and compresses applied. Under the influence of the rubber the eczema perspires freely, and twenty-four hours after the application a solution of nitrate of silver 1:40 is applied. This solution is allowed to dry on the surface of the skin, and the rubber is replaced. The following day a 1:30 solution is used, and after two or three days the physician is able to use a 1:15 solution. Generally no inflammatory reaction is perceptible, and in such cases a day may be skipped, and the inflammation goes down. If at the end of this treatment the skin is slightly retracted, the use of oxide of zinc ointment is sufficient to relieve this condition. The author adds that he knows of no treatment which is so apt to produce rapid and beneficial results.

When the acute period is over and the edema is disappearing, the treatment is to be modified to a certain extent, and as an example the author cited what should be the best treatment in a case of eczema of the hands. Complete asepsis is a sine qua non and should be obtained by applications of compresses with boiled water, or rather water charged with boric acid or bicarbonate of soda in five-per-cent doses. In two or three days the asepsis is complete, and even if there are any traces left of boils, for instance, the eczematous surface may be cauterized with the exception of the afflicted part. Cauterization is then made with a saturated solution of nitrate of silver, and immediately after a small crayon of pure zinc is passed over the surface. A black precipitate of silver is thus produced. The surface dries very rapidly and remains black three or four days. A second cauterization is made after three days, a third the sixth day. So far the author’s experience has not shown him any untoward results. Between two applications some heavy ointment is applied, such as:

Vaselin, 10 grammes;
Oxide of zinc, 5 grammes;
Talc, 5 grammes.

Or,

Vaselin, 10 grammes;
Dermatol, 6 grammes.

Amelioration is very rapid, but a thing to be noted is that on no account should the patient wash his hands; he can cleanse them with bread or with almond paste. After a time the epidermis comes back to its original condition, but there remains a certain thickening which cannot be removed by the use of nitrate of silver. In such cases the application of a salicylic ointment is useful; for instance:

Lanolin,
Vaselin, 1 dram 6 grammes;
Oxide of zinc, 3 grammes;
Salicylic acid, 50 centigrammes.

Or,

Glycerite of starch, 20 grammes;
Oil of cade, 2 grammes;
Oil of white birch, 1 gramme;
Extract of quills, 2 q. s.;
Juniper extract, 5 drops;
Vanillin, 3 centigrammes.

The latter preparation is rather disagreeable on account of its odor.
ROME LETTER.

BY J. J. EYRE, M.D.

The Health of the Pope—Partial Resection of the Abdominal Sympathetic, Performed by Professor Ruggi, of Modena—Hyposulphite of Sodium and of Mercury for Hypodermic Injections in Syphilis.

The late illness of the pope has given rise to so much interest throughout the world, and to so many false statements as to his condition at the time of the operation and subsequently, that the following account obtained from the very best sources may not be devoid of interest for the readers of the Therapeutic Gazette. On February 21, Leo XIII, who completed his eighty-ninth year on March 2 ult., was taken ill with general malaise, rise of temperature, and severe pain in a cyst which had existed in the left flank, immediately above the crest of the ilium, for upwards of twenty-five years without causing much, if any, inconvenience. The holy father's physician, Professor Lapponi, on his visit the following morning, found that his august patient was suffering from inflammation of the cyst, and he requested a consultation with Professor Mazzoni, libero docente of special pathology in the University of Rome, and nephew of the late Professor Mazzoni, the predecessor of Professor Durante in the chair of surgery of the same university. The result of the consultation was that Mazzoni enucleated the cyst on the morning of March 1, having previously anesthetized the part with the ether spray and the subcutaneous injection of cocaine. This method of local anesthesia was adopted because it was not considered advisable to administer chloroform to the pope owing to his great age. Leo XIII bore the operation admirably, and in the evening the temperature had fallen to 99.5° F., from 102° F. in the morning; the pulse was good, and the general condition satisfactory. Professor Mazzoni has told me that the cyst was hemispheric, of the size of a large citron or of a fetal head at term; it was not suppurating. After the extirpation Mazzoni plugged the cavity and brought the edges of the skin wound together with strips of plaster, as the doctors thought that the introduction of stitches would be too painful. The following day the tampon was removed and the edges brought together with plaster. Since then the pope has made an uninterrupted recovery. For about a month after the opera-

tion he naturally suffered from some weakness, due to the loss of blood and the effects of the operation, but on April 16 his holiness was so well that he was able to be present in St. Peter's at the mass celebrated in commemoration of the twenty-first anniversary of his coronation, notwithstanding that the Rome correspondent of some of the English papers had stated a few days before that he was in a hopeless condition! Leo XIII bore the fatigue and excitement wonderfully well, which is somewhat surprising considering his great age, his apparently very fragile and pallid appearance, which is habitual, and the extraordinary enthusiasm displayed by the 50,000 people present when the pope entered and left the Basilica.

At the last meeting of the Medico-Chirurgical Society of Bologna Dr. Nasi read a paper on "Partial Resection of the Abdominal Sympathetic, Performed by Professor Ruggi in the Surgical Clinic of Bologna." The reader stated that Professor Albertotti had already communicated to the Society that Ruggi had performed several sympathectomies of the neck for the treatment of glaucoma. These, to the number of six, had been performed in the ophthalmic clinic of Albertotti. Ruggi, having observed how just was the observation already made that the glaucomatous sufferers experienced immediate relief from their sufferings with resection of the sympathetic in the neck, thought of attempting a similar operation for cases of abdominal neuralgia rebellious to the ordinary methods of treatment. On February 23 Ruggi performed resection of the abdominal sympathetic in a woman who for a long time had suffered from a very acute pain in the left flank, which was associated with a feeling of heat and a trembling of the whole of the left half of the body. These phenomena having increased, the patient was admitted to the Clinica Chirurgica in December, 1898, where it was found that she was suffering from right ovarian and left salpingo-ovariitis, and Ruggi performed left salpingo-ophorectomy and right oophorectomy. After the operation the patient was better, but in February she came again to the clinic, as the pain had returned as severely as at first.

The second patient operated upon with resection of the abdominal sympathetic had been formerly treated by other surgeons with scraping of the uterine cavity and amputation of the neck, and in the surgical clinic had been subjected to bilateral ovarian resection and shortening of the round ligaments
with Ruggi's method, because she suffered from double ovaritis with marked retroflexion. But the suffering that this patient also endured from continuous pain over the whole abdomen, and radiating to the lower limbs and to the right upper limb, obliged her to return to the clinic, where she had undergone vaginal hysterectomy on January 4 for extremely painful chronic metritis. This operation, however, did not relieve the patient, and on March 6 resection of the abdominal sympathetic was performed.

Professor Ruggi performs this operation in the following manner: The patient is placed in Trendelenburg's position; the abdomen is opened from the pubes to the umbilicus, and even beyond if the patient be very fat. The intestines being displaced upwards, the pelvis is easily dominated; the operator notes what is found there, and having observed nothing abnormal, he proceeds directly to the resection of the nerve branches. The surgeon being on the left, he generally commences from this side the quest of the nervous bundle of the sympathetic which forms the so-called spermatic plexus, that comes from the renal plexus and in part from the aortic plexus; it accompanies the spermatic artery and is distributed on each side in the male to the testicle, and the epididymis, in the female to the ovary and the superior part of the uterus. With this scope, then, the operator divides the peritoneum opposite the spermatic artery and the pampiniform plexus, and having isolated the neurovascular bundle, which is very easily detached from the underlying parts, he passes it a gauze band of the breadth of two fingers, capable of raising it and keeping it well distended. By this means the spermatic artery can be uncovered with care, and in Ruggi's cases it was isolated, ligatured above, and divided, while the remainder of the neurovascular bundle, formed of the inferior portion of the artery, the vein, the nerves, and the lymphatics, was ligatured below and partially extirpated. Having thus interrupted the vessel communications above and below, the operator can be certain of avoiding both arterial and venous hemorrhage, and he also has the certainty of having divided all the nerves which accompany those vessels, without constricting them above with a ligature that might irritate them with its necessary constriction.

Both patients thus operated upon—the first after twenty-two days, the second after eleven days—had an excellent postoperative course, and were completely free of the sufferings by which they had been for so long a time tormented.

Dr. Miceli, of Messina, after many researches directed to the scope of obtaining a preparation of mercury very soluble in water, of readily efficacy, and which would not provoke either pain or induration in the parts where it has to be injected, has succeeded in preparing his antisyphilitic hypodermic solution, which he says fully responds to the above requirements. Miceli's preparation is a new salt (double hyposulphite of sodium and of mercury), in the form of a solution in distilled and sterile water. The liquid is without color or odor; each cubic centimeter contains one centigramme of the salt, equivalent to about nine milligrammes of metallic mercury. The solubility of this salt exceeds that of all other salts of mercury—in fact, it has a solubility of 50.4 per cent, and does not produce mercurial stomatitis. Thus in fifteen cases treated by the author it never appeared, excepting in a patient who had had twenty-five injections in as many days. The hypodermic solution never produces indurations, is more ready in its efficacy than the other preparations of mercury, and owing to the hyposulphite of sodium it contains (whose antisyphilitic virtue has been extolled by many authors, including Sullien and Radcliffe) is also reconstituent; indeed, the patients subjected to this treatment increased in weight. Miceli's solution is carefully prepared under his immediate surveillance, and is put up in bottles, each sufficient for twelve injections. It is used with the rules which regulate the injections of other mercurial preparations.

QUININE IN MALARIA.

To the Editor of the Therapeutic Gazette.

SIR: This communication is for practitioners, and deals not with theoretical knowledge; it is only a clinical note, chiefly from bedside experience.

Natchez is on a bluff overlooking the lowlands of Louisiana, and from her swamps and bayous we draw our greater share of cases of typical malaria, and all cases of hematuria.

In the simple intermittent fever quinine is undoubtedly a specific; but when cured, and no change is made in the environments—as with the cotton planter of the lowlands on both sides of the river—reinfection is certain to take place, and in these cases quinine, in usual doses, is extremely dangerous. All
cases of hematuria of malarial origin occurring under my observation (in whites) have been due to reinfection and followed the protracted use of quinine. One or two grains dissolved in half a drachm of dilute phosphoric acid is of benefit in preventing a second invasion, and is a tonic of superb power. I use something like the following:

- B. Quinine sulphatis, 3 iij;
- Tinctura ferri chloridi, 3 i;
- Acidii phosphorici dill., 3 iv;
- Spiritus frumenti, q. s. ad 3 viij;
- M. S.: Teaspoonful in one-third glass of water at meals.

Now as to the treatment of hematuria, when found. I use ergot in half-drachm doses every three or four hours, and strychnine hypodermically in full doses. I flush the bowels with the hyposulphite of sodium, and I have found an emulsion of turpentine of service in some cases. If the patient is restless and fretful, an enema of sixty grains of potassium bromide is of unquestioned utility. The patient is always anxious, and his mind is very quick. To allay his anxiety and keep his spirits up is a task for us to perform; but it must be done, and a stimulant is a great aid. For this panaceptum will be found useful. When the urine clears up and fever and weakness disappear, strychnine and arsenic should be given as a tonic, and elixir of calisaya or tinctura chinchona compositus at meals as an appetizer. Above all, change the location of the patient.

I have treated eight cases thus, or about as indicated, with no deaths. Three of the cases were caused from catching fish from shallow mud-holes—ponds. The persons would wade out in the pond and spear the fish. These ponds are common in flat countries after an overflow, and as they gradually get smaller, towards the last they literally swarm with a fish of the "sucker" variety. These, half-cooked, are almost certain to produce a variety of ailments, and among them hematuria, in which we also find epistaxis, hematemesis, and occasionally hemorrhage from the rectum—in fact, a general tendency toward hemorrhage.
